Salt. The basic raw material for the mercury cell and membrane cell processes is usually solid salt. This may be obtained from three sources: rock salt, solar salt, or vacuum-evaporated salt from purifying and evaporating solution-mined brine.

In the United States and Europe, rock salt is most commonly used. The most important impurities are shown in Table 3. The concentrations of these impurities depend on the method of production and on the different grades: crude rock salt, prepared rock salt, and evaporated salt. Solar salt is used in Japan and many other parts of the world, the most important sources being Australia, Mexico, China, Chile, India, and Pakistan. The salt produced by solar evaporation is usually much less pure than rock salt. In a few cases the salt may be obtained from other processes, such as caustic soda evaporation in the diaphragm process.

A new upgrading process (Salex) has been developed by Krebs Swiss [48]. It removes the impurities by selective cracking of the salt crystals and a washing process. Salt losses are minimized, and the purity exceeds 99.95 % NaCl.

Table 3. Impurities in rock salt and sea salt, wt %

	Rock salt	Sea salt
Insolubles	≤ 2	0.1 – 0.3
Water	≤ 3	2.0 – 6.0
Calcium	0.2 – 0.3	0.1 – 0.3
Magnesium	0.03 – 0.1	0.08 – 0.3
Sulfate	≤ 0.8	0.3 – 1.2
Potassium	≤ 0.04	0.02 – 0.12

Brine Resaturation. In older plants, the open vessels or pits used for storing the salt are also used as resaturators. The depleted brine from the cells is sprayed onto the salt and is saturated, the NaCl concentration reaching 310 – 315 g/L. Modern resaturators are closed vessels, to reduce environmental pollution [49], which could otherwise occur by the emission of a salt spray or mist. The weak brine is fed in at the base of the resaturator, and the saturated brine is drawn off at the top. If the flow rates of the brine and the continously added salt are chosen carefully, the differing dissolution rates of NaCl and $CaSO_4$ result in little calcium sulfate dissolving within the saturator [50]. Organic additives also reduce the dissolution rate of calcium sulfate [51]. The solubility (g per 100 g of H_2O) of NaCl in water does not increase much with temperature (t, °C), whereas the solubility of KCl does:

t	0	20	40	60	80	100
c_{NaCl}	35.6	35.8	36.4	37.0	38.5	39.2
c_{KCl}	28.2	34.4	40.3	45.6	51.0	56.2

Brine Purification. In mercury cells, traces of heavy metals in the brine give rise to dangerous operating conditions (see page 15), as does the presence of magnesium and to a lesser extent calcium [52]. In membrane cells, divalent ions such as Ca^{2+} or Mg^{2+} are harmful to the membrane. The circulating brine must be rigorously purified to avoid any buildup of these substances to undesirable levels [7]. Calcium is usually precipitated as the carbonate with sodium carbonate; magnesium and iron, as hydroxides with sodium hydroxide; and sulfate, as barium sulfate.

The reagents are usually mixed with weak brine and added to the brine stream at a controlled rate. If solar salt is used, treatment costs may be reduced by prewashing the salt [53]. In order to precipitate calcium at low pH, sodium bicarbonate [54] or phosphoric acid [55] can be added.

The sulfate content can be reduced without the use of expensive barium salts by discharging a part of (purging) the brine [56], by crystallization of $Na_2SO_4 \cdot 10\,H_2O$ on cooling the brine stream [57], by precipitation of the double salt $Na_2SO_4 \cdot CaSO_4$ [58], by an ion-exchange process, or by membrane nanofiltration [59]. Hoechst [60] has a process for recovering barium sulfate of pure pigment quality by precipitation under acid conditions. Chlorate buildup can be avoided by addition of sodium metabisulfite $Na_2S_2O_5$ [61].

After stirring for 1 – 2 h, the precipitated impurities are removed by filtration alone or by sedimentation followed by filtration. Sedimentation is carried out in large circular settling tanks, from which the slurry is removed by mechanical raking equipment, e.g., Clariflocculator, Cyclator, or Dorr thickener. Filtration is carried out with a sand filter, a pressure-leaf filter with filter cloths of chlorine-resistant fabrics, or candle filters automatically cleaned by backflow of brine. The filter is cleaned by water jets, vibrating, or shaking. The separated filter cake is concentrated to 60 – 80 % solids content in rotary drum vacuum filters or centrifuges before disposal. Any soluble material present may be removed from the sludge by washing with water. Barium salts may be recovered by treating with sodium carbonate under pressure [62]. The purified brine should contain ideally $c_{Ca} < 2$ mg/L, $c_{Mg} < 1$ mg/L, and $c_{SO_4} < 5\ g/L$.

In the diaphragm process, the removal of sulfate is not always necessary because SO_4^{2-} can be removed from the cell liquor as pure Na_2SO_4 during the concentration process. In the membrane process, the brine must be purified to a much higher degree to avoid the deterioration of the membrane. The Ca^{2+} and Mg^{2+} concentration must be < 0.02 ppm (20 ppb), so a second, fine purification step is required (see Section 7.2.1).

Before the brine enters the electrolysis cells, it should be acidified with hydrochloric acid to pH < 6, which increases the life of the titanium anode coating, gives a purer chlorine product with higher yield, and reduces the formation of hypochlorite and chlorate in the brine.

Brine Dechlorination. In the mercury and membrane processes, the depleted brine leaving the cells must be dechlorinated before resaturation. Further acidification with hydrochloric acid to pH 2 – 2.5 reduces the solubility of chlorine by shifting the equilibrium point of hydrolysis and inhibits the formation of hypochlorite and chlorate. Chlorine discharged in the anolyte tank prior to dechlorination may be fed into the chlorine system. The dissolved chlorine of the brine then is still 400 – 1000 mg/L, depending on pH and temperature. The brine is passed down a packed column or sprayed into a vacuum of 50 – 60 kPa, which reduces the chlorine concentration in the brine to 10 – 30 mg/L. The vacuum is produced by steam jet or liquid-ring vacuum pump. The pure chlorine gas obtained is fed into the chlorine stream.

The water that evaporates from the dechlorinated brine is condensed in a cooler. The condensate, which may be chemically dechlorinated, is returned to the brine circulation system if necessary to maintain the volume of the brine circuit. If necessary, the remaining chlorine content can be further reduced by blowing with compressed air, by a second vacuum treatment, by treatment with activated carbon [63], or by chemical treatment with hydrogen sulfite, thiosulfate, sulfur dioxide, or sodium hydrogensulfide.

Brine Monitoring. The sodium chloride concentration in the brine is determined by density measured by equipment involving radioactive isotopes, vibration techniques, hydrometry, or weighing.

The pH following alkali or acid additions is determined with glass electrodes, and the redox potential following chlorine removal is determined with metal electrodes. Excess OH^- and CO_3^{2-} ions ensure adequate precipitation of dissolved calcium, iron, and magnesium. After filtration, a test sample of 100 mL should require 4 – 6 mL of 0.1 N acid to reach the phenolphthalein end point and a further 0.5 – 1.5 mL to reach the methyl orange end point. Inadequate filtration is detected by turbidimetry in transmitted light or by the Tyndall effect. Calcium and magnesium are determined hourly, and chlorate and sulfate about once per day, all by titration.

4.2. Electricity Supply

Since 1960 the direct current for electrolysis has been provided exclusively by silicon rectifiers. A set of rectifiers can supply up to 450 000 A. Voltages up to 4.0 kV per diode are feasible, but usually for safety, a peak a.c. voltage of 1500 V, corresponding to a d.c. output of 1200 V, is not exceeded. Liquid cooling of the diodes permits a compact design, and self-contained equipment reduces leakage losses. Modern membrane cell plants also use continuously variable thyristor converters in place of silicon diodes [64].

Rectification equipment is required to provide steady direct current at a voltage determined by the cell room. The current must remain steady even though the voltage is varied both by the operating condition of the cells and by the number of cells operating. The rectifier equipment usually consists of

transformer capable of variable output voltage with adequate compensation for changing input voltage
silicon rectifiers or thyristors
constant-current control gear
transducers for metering and control
control panels
isolators
cooling equipment
ancillary safety and monitoring equipment

Each set of rectifiers is connected through high-voltage switchgear to the three-phase supply [65]. Smaller units use a 10 – 30 kV supply, but large units can be connected into the high-voltage power system (> 100 kV) [66].

The unit cost of the d.c. supply decreases with increasing voltage and current. A plant is therefore most economical when as many high-current cells as possible are connected in series [67]. Total currents of 450 000 A are achieved. The switches for short-circuiting the cells are designed for 10 000 – 30 000 A and are operated by compressed air, hydraulically, or by spring action. Erosion of the main contacts is dealt with by using replaceable pre-contacts [68]. The contacts are protected from corrosion by installation in vacuum housings.

The current in the bus bars or in anode rods can be measured by means of iron-free transportable equipment with an accuracy of ca. 1 % [69].

5. Mercury Cell Process

The clean separation of chlorine from the cathode products is possible because of the high overvoltage of hydrogen at the mercury electrode. Hydrogen and sodium hydroxide are not produced at the cathode; instead, sodium is produced and dissolves in the mercury as an *amalgam.* The liquid amalgam is removed from the electrolytic cell to a separate reactor, called the decomposer or denuder, where it reacts with water in the presence of a catalyst to form the sodium hydroxide and hydrogen gas. The process may also be used to produce potassium hydroxide by feeding the cell with potassium chloride solution, although this is much less common. The sodium hydroxide is produced from the denuder at a concentration of ca. 50 wt %; the maximum value is 73 wt %. The hydroxide solution is very pure and almost free from chloride contamination.

The process was developed in 1892 almost simultaneously by H. Y. Castner and C. Kellner and used on an industrial scale, although the amount of chlorine produced remained relatively small until 1930, when the rapid growth of the rayon (artificial silk) industry, especially in Germany, increased the demand for pure

chloride-free sodium hydroxide solution. At this time, the horizontal high-current cell was developed and output increased rapidly. The development work in Germany was described in the FIAT final reports, published after World War II, and this led to widespread use of the process in Europe and Japan [70]. In the United States, the mercury cell process became more widespread, increasing its share of chlorine production from 3 – 4 % in 1945 to 20 % in 1960, reaching a maximum of 27 % in 1970.

The development of the mercury cell can be followed in the technical data: the cell current increased from 3.4 kA in 1895 to ca. 30 kA in 1945, 200 kA in 1960, and 450 kA in 1970. The current density rose from 2 kA/m^2 in 1950 to the current maximum of 15 kA/m^2. The cell area increased over the same period from ca. 7 m^2 to 37.5 m^2, while the *k*-factor (specific voltage coefficient, see page 16) was reduced by 50 %.

Since 1972 the importance of the mercury cell has decreased. Increasing concern about the effect of mercury on the environment has led to a considerable increase in the number and variation of statutory regulations that affect the mercury cell process.

In particular, widespread concern about cases of mercury poisoning in Japan, which were not related to the mercury cell process, caused the process to be legally banned since 1972. However, conversion to the alternative processes was delayed because of demand for low-chloride sodium hydroxide and because of the anticipated advantages of the rapidly developing membrane cell process. The last remaining mercury cell installations for NaCl were closed in 1986.

In the other countries, existing mercury cell plants are still in operation, but official regulations and uncertainty about possible further legal restrictions have hindered expansion.

In Europe and the United States great efforts are being made to develop methods of protecting the environment from mercury (see Section 5.3.5). These measures have greatly reduced emissions of mercury into the atmosphere and into wastewater to the extent that the present levels of emitted mercury are negligible in comparison to those arising from natural sources, such as volcanic action, geological erosion, or other nonnatural sources such as fuel combustion or metallurgical processes.

In 1984, the mercury cell process accounted for 45 % of world chlorine production [71]. Since then no new plants have been built. In the coming decades most of the existing mercury cell plants will be shut down or converted to membrane cell technology. Only plants with speciality products such as extremely pure sodium hydroxide, potassium hydroxide, alcoholates, and dithionites will use the mercury process in future. These plants will meet the highest emission control standards.

5.1. Principles

The cathode reaction

$$Na^+ + e^- + Hg_x \rightarrow NaHg_x$$

forming sodium amalgam, is followed by the decomposition reaction in a separate reactor

$$2\,NaHg_x + 2\,H_2O \rightarrow 2\,NaOH + H_2\,(g) + 2\,Hg_x$$

Process Description (Fig. 13). Mercury flows down the inclined base of the electrolytic cell (A). The base of the cell is electrically connected to the negative pole of the d.c. supply. On top of the mercury and flowing cocurrently with it is a concentrated brine with a sodium chloride content of ca. 310 g/L at the inlet. Anodes are placed in the brine so that there is a small gap between the anode and the mercury cathode. The concentration of the amalgam is maintained at 0.2 – 0.4 wt % Na, so that the amalgam flows freely (Fig. 14). The chlorine gas and depleted brine (270 g/L) flow out of the cell, either separately or as a two-phase mixture separated later in the process. The amalgam flows out of the cell through a weir and into the decomposer. The amalgam may be passed through a water wash between the cell and the decomposer to remove traces of sodium chloride. The amalgam flows through the decomposer countercurrent to a flow of softened or demineralized water in the presence of a catalyst to produce sodium hydroxide solution and hydrogen. Stripped of its sodium, the mercury flows out of the lower end of the decomposer and is recirculated through a pump back into the cell.

Figure 14. Freezing point curves of sodium amalgam and potassium amalgam

Anode Reactions. The oxidation of chloride ions to chlorine gas has a standard potential of 1.358 V. In a 300 g/L sodium chloride solution at 70 °C, the reversible reaction potential is reduced to 1.248 V [15, p. 339]. Some side reactions occur, such as the oxidation of OH^- and SO_4^{2-} ions and the electrochemical formation of chlorate ions. Nonelectrochemical reactions also take place in the region of the anode, such as hypochlorite formation (because of hydrolysis of chlorine) and chlorate formation. All of these side reactions represent a loss of efficiency.

Cathode Reactions. The standard potential of the hydrogen-liberating reaction is 0 V, which is considerably higher than the potential for the formation of 0.2 wt % sodium amalgam, − 1.868 V. However, hydrogen is not liberated at the mercury surface because the reaction is kinetically inhibited. Mainly sodium ions are discharged. At the sodium chloride concentrations used, the reversible potential is reduced by ca. 0.2 V. (Exact values of the discharge potential are given as a function of the sodium concentration in the amalgam, the sodium chloride concentration in the brine, and the temperature [72].) Electrochemical side reactions occur: the reduction of chlorine molecules or hypochlorous acid and the liberation of hydrogen gas. In addition, sodium in the amalgam can react directly with free chlorine, or chlorite and chlorate ions can be reduced to chloride by the action of nascent hydrogen at the cathode. All of these side reactions represent a loss of efficiency, normally ca. 2 – 4 % under good operating conditions.

Contamination of the system by heavy metals can lead to a reduction of the hydrogen discharge potential at the mercury cathode, thus increasing hydrogen liberation, and reducing amalgam formation [73]. The hydrogen concentration in the chlorine can increase to the point at which the cell and downstream chlorine handling equipment contains explosive mixtures. The probability of such problems is estimated by a hazard analysis of an existing plant [74 – 76].

The cell system is sensitive to trace quantities of catalysts in the brine, for example, vanadium, molybdenum, and chromium at the 0.01 – 0.1 ppm level or iron, cobalt, nickel, and tungsten at the parts per million level. Magnesium, calcium, aluminum, and barium are also active at the parts per million level.

In addition, relatively high concentrations of sodium in the amalgam (> 0.5 wt %) can cause increased hydrogen evolution in the cells. Potassium chloride electrolysis is considerably more sensitive to both catalysts and high concentration in the amalgam than the sodium chloride process.

Current Efficiency. The theoretical electrochemical equivalents representing the materials produced or consumed in the electrolysis of sodium chloride or potassium chloride brines are given in Table 4. In practice, the yield is ca. 95 – 97 % of the theoretical value, owing to side reactions at the electrodes and in the electrolyte. With activated titanium anodes, the yield is largely independent of the distance between the electrodes.

The decrease in salt concentration Δc is determined by the current I, the brine flow rate M, and the electrochemical equivalent f.

$$\Delta c = f\,I/M$$

The usual units are c in g/L, f in kg kA^{-1} h^{-1}, I in kA, and M in m^3/h.

Cell Voltage. The d.c. voltage across the cell circuit is determined by five factors:

1) The reversible decomposition voltage of the salt
2) The overpotentials of the chlorine and alkali metal at the electrodes
3) The voltage drop in the electrolyte
4) Voltage losses in the bus bars, switches, electrical conductors, anode materials, and cathode
5) The operating current density of the cells

Factor 1. The reversible decomposition potential of NaCl under standard conditions is $E^\circ = 3.226$ V (KCl $E^\circ = 3.234$ V). Under the operating conditions $c_{\mathrm{NaCl}} = 290$ g/L, $c_{\mathrm{amalgam}} = 0.15$ %, and 70 °C, the reversible decomposition voltage is $E = 3.095$ V [77].

Factor 2. The overpotential of chlorine depends on the material and shape of the anodes. At the high current densities (10 kA/m^2) present in modern cell rooms, the overpotential can reach several hundred millivolts, outweighing the effect of concentration changes in the electrolyte (concentration polarization) [78] and the retarding effect that formation of molecular chlorine has on the process of ion discharging [79]. Chlorine gas bubbles cover part of the anode surface, thereby increasing the current density at the free surface. The anode is designed so that the gas bubbles are liberated as quickly as possible. The rapid removal of these gas bubbles from the reaction zone is one of the advantages of titanium anodes over graphite anodes [80].

The overpotential of sodium on the amalgam cathode is caused by the limited diffusion rate of the liberated sodium atoms into the amalgam, but it is small compared to the chlorine overvoltage.

Factor 3. The specific conductivity of sodium chloride solutions increases with concentration and temperature (Fig. 15), but is independent of pH over the range 2 – 11. The brine normally enters the cells at 60 – 70 °C and leaves the cells at 75 – 85 °C. The conductivity of potassium chloride solutions at 70 °C is 30 % greater than that of sodium chloride solutions. Chlorine gas bubbles in the electrolyte increase the resistance between anodes and cathode. Better circulation of the electrolyte in the gap between electrodes allows more rapid removal of gas bubbles, thus reducing the voltage.

Factor 4. The voltage losses in the cell room are minimized by compactly arranging the cells, which shortens the current path. The relatively low conductivity of steel cell bases can be improved by copper or aluminum fittings. These measures also reduce problems caused by magnetic fields, which occur in wide cells [81].

Factor 5. In practice, cell current density and cell voltage have a linear relationship. The slope of the line is termed the specific voltage coefficient or k-factor, a useful measure of the specific energy requirement of cells produced by different manufacturers.

Table 4. Electrochemical equivalents f, kgkA^{-1}h^{-1}

Element	Element produced	Salt required	Alkali produced
Na	0.8580	2.1810 (NaCl)	1.4923 (NaOH)
K	1.4586	2.7816 (KCl)	2.0931 (KOH)
Cl_2	1.3228 (0.4115 m^3 STP)		
H_2	0.0376 (0.4185 m^3 STP)		

Figure 15. Specific conductivity of sodium chloride solutions

The cell voltage is given by $U_{\text{cell}} = 3.15 + kJ$, J = current density, kA/m^2, k = specific voltage coefficient, V m^2 kA^{-1}.

Computer-controlled cells with activated titanium anodes are run with k-factors from 0.085 to 0.11. The corresponding cell voltages at 10 kA/m^2 are 4.00 – 4.25 V (Fig. 16).

Figure 16. Cell voltage and specific energy consumption per tonne of Cl_2 versus cell current density

In addition to the d.c. voltages considered above, there are energy losses across the transformer and rectification equipment. All cell installations use a.c. power, which is rectified by silicon diodes in which the energy losses are minimized by operating at greater than 100 V. This voltage is achieved by operating at least 25 cells in series.

Energy Consumption. To operate a cell installation economically, the consumption of d.c. electrical energy per unit mass of product must be minimized. The specific energy consumption w is given by

$$w = 1000\, U_{\text{cell}}/a\, f$$

where w = kWh/t, a = yield factor or current efficiency, f = electrochemical equivalent, kg kA^{-1} h^{-1}

For example, if the cell voltage U_{cell} is 4.20 V and the current efficiency is 0.970, then ca. 3275 kWh is required to produce 1 t of chlorine + 1.13 t of NaOH. Since af is almost a constant, the specific energy consumption per tonne of chlorine w is effectively proportional to the cell voltage. In that case, w also depends on the cell current density (see Fig. 16). In the example, w = 3275 kWh corresponds to 10 kA/m^2.

The total energy requirement per tonne of Cl_2 must also include the transformer and rectifier losses (30 – 40 kWh/t) and the energy requirements of all of the ancillary equipment (120 – 160 kWh/t).

A mathematical model of the cell has been described [82].

Decomposition of the Amalgam. The amalgam is decomposed in horizontal decomposers, alongside or beneath the cell, or more often since ca. 1960 in vertical decomposers or denuders. The energy stored in the amalgam

has an emf of ca. 0.8 V. The hydrogen overpotential at the amalgam prevents spontaneous decomposition in contact with water, and a catalyst (depolarizer) must be used. The overall decomposition reaction is

$$2\,NaHg_x + 2\,H_2O \rightarrow 2\,NaOH + H_2 + 2\,Hg_x$$

and takes place in two stages, first as an anode reaction at the surface of the amalgam

$$2\,Na \rightarrow 2\,Na^+ + 2\,e^-$$

and then as a cathode reaction on the catalyst surface, where the water is decomposed

$$2\,H_2O + 2\,e^- \rightarrow 2\,OH^- + H_2$$

Industrial decomposers are essentially short-circuited electrochemical primary cells (Fig. 17). The most common *catalyst* is graphite [*7782-42-5*], usually activated by oxides of iron, nickel, or cobalt or by carbides of molybdenum or tungsten. The hydrogen overpotential on graphite (0.5 – 0.6 V at 2 kA/m^2 and 80 °C) increases with current density and decreases with temperature; therefore, the decomposer should be operated at as high a temperature as possible [83]. Good catalyst material must meet many requirements: resistance to alkali solutions, hydrogen, and mercury; low hydrogen overpotential; good electrical conductivity; long-lasting activity; wettability by amalgam; and incapability of amalgamation.

Figure 17. Principle of amalgam decomposition

Attempts to recover some of the energy stored in the amalgam by creating an electrical circuit by using the catalyst as the anode separated from the amalgam or by using the amalgam electrode with an oxygen gas diffusion electrode have so far had no practical outcome [84].

Horizontal decomposers are ducts with a rectangular cross section, which are installed with a 1 – 2.5 % slope near to or underneath the cells. The amalgam flows in a stream ca. 10 mm in depth, and the sodium content is thereby reduced to < 0.02 wt %. The catalyst consists of graphite blades 4 – 6 mm thick, which are immersed in the amalgam in a lengthwise direction (Fig. 18, also see Fig. 13 B). The water for the reaction, which is softened or demineralized by ion exchange, flows in the direction opposite the amalgam and is removed as 50 % caustic alkali solution. The hydrogen gas is cooled as it leaves the decomposer so that any condensed water and mercury run back into the decomposer. Advantages of the horizontal decomposer are serviceability, simple construction, and a pure product that is low in mercury. However, horizontal decomposers require a greater mercury inventory than vertical decomposers.

Figure 18. Cross section through a horizontal decomposer a) Amalgam; b) Bolt; c) Graphite blades; d) Hydrogen; e) Sodium hydroxide solution; f) Decomposer casing; g) Spacers

Vertical decomposers are designed as towers [85] containing packings of activated graphite spheres or other shapes 8 – 20 mm in diameter. The towers are packed 0.6 – 0.8 m high. The cross section of the tower is 0.35 m^2 per 100 kA of cell current. The amalgam is fed in via an overhead distributor, and the mercury is pumped

from the base of the tower back to the cell by a closed centrifugal pump (see Fig. 13C). The water for the reaction is fed into the base of the tower and flows upward counter to the amalgam. The 50 % caustic alkali solution flows out at the top. The smaller volume of the vertical decomposer leads to higher product temperature because of the greater energy intensity of the system. Cooling the hydrogen is essential. Compared with the horizontal decomposer, the amount of space required is small, and the mercury inventory is small, but the caustic alkali contains more mercury.

In alternative decomposition reactions, other products may be obtained from the amalgam in place of sodium or potassium hydroxide solutions [10, p. 518], [86]: sodium sulfide from sodium polysulfide solution, alcoholates from alcohols, sodium dithionite from sodium hydrogen sulfite, hydrazobenzene or aniline from nitrobenzene, adiponitrile from acrylonitrile, and alkali metals by distillation.

5.2. Mercury Cells

During the first decades after the rocking cells of Castner and Kellner were first commissioned, considerable efforts were made to develop suitable materials for the cells and the anodes. A large number of cell configurations were tested, resulting in the development of the continuous cell. Since 1950, the cell areas and the specific load were increased considerably.

In 1972, the changeover from graphite to metallic anodes began, with a parallel development of computer monitoring and control, leading to improved short-circuit protection and a reduction of the specific energy consumption by computer-controlled anode adjustment, of great significance in view of the drastic increase in electricity costs in the late 1970s. In the years following 1972, producers operating the electrolysis plants also concentrated on the development and installation of devices to reduce mercury emissions.

The cells currently available possess a number of common features. The mercury flows over a steel base that has a slope of 1.0 – 2.5 %. The flanged side walls are lined with rubber. The cell covers are mostly steel, lined with rubber or titanium on the underside, but they may also be rubberized fabric. The anodes, generally made of activated titanium, hang in groups from carrying devices that can be varied in height manually, hydraulically, or by motor-operated lifting devices. Each cell can be short-circuited externally by a switch. The cell bus bars are usually copper. The anodes are protected from internal short circuits by means of electronic monitoring systems. The size of the cells can be varied within a broad range to give the desired chlorine production rate. Computer programs optimize the cell size, number of cells, and optimum current density as a function of the electricity cost [87] and capital cost.

For comparison, a list of cells manufactured by leading engineering firms and cell characteristics is given in Table 5. Cathode surface areas are ca. 17 – 30 m^2, and nominal currents are ca. 170 – 300 kA [32, p. 204].

5.2.1. Uhde Cell

The Uhde cells (Fig. 19, also see Fig. 22) are available with a cathode surface area 4 – 30 m^2 for chlorine production rates 10 – 1000 t/d for the complete cell installation. The brine flows in via an inlet box fitted with two pipes for the removal of chlorine. The weak brine is removed at the end of the cell. The solid cover is fixed to the side walls by clamps. The anodes are suspended in groups in carrying frames supported near the cells on transverse girders with lifting gear. The anode rods are raised and lowered within a bellows seal. Short copper bus bars between the cells also serve for shunt measurement of the anode currents. The electric current is brought in above the cell covers via flexible copper straps that run immediately above the anode rods and are bolted to them. The compressed-air switches are situated under the cells. The cell bottom is usually a current conductor when cells are short-circuited, but in wide, heavily loaded cells the cathode current is carried by copper bus bars to prevent the occurrence of strong magnetic fields, which could interfere with the amalgam flow. The automatic equipment for protection and adjustment of the anodes depends on the shunt measurement of the currents and is controlled by a central computer. In this way, an optimum k-factor is selected for each cell. The vertical

Table 5. Characteristics of modern mercury cells

Characteristic	Manufacturer

decomposers are provided with hydrogen coolers and are situated at the end of each cell. The amalgam flows into the decomposer under the force of gravity [88].

5.2.2. De Nora Cell

The size of the De Nora cell (Fig. 20, also see Fig. 23) varies from 4.5 to 36 m^2, corresponding to electric currents from 45 to 400 kA. The cover is a flexible multilayer sheet of elastomer spread over the cell trough. This cover is supported by the anode rods and seals them. The DSA anodes (see Section 8.1) are held rigidly in strong carrying frames, which are automatically adjusted by electric motors. Individual anode adjustment is not provided. The anode rods are individually connected by flexible copper straps to the an-

ode bus bars. The cathode current is carried by copper bus bars. Devices for the improvement of brine circulation and gas removal within the cells reduce specific energy consumption. Consequently, the reduction in brine concentration can be increased from the usual 35 – 40 g/L to 60 – 70 g/L, and the brine circulating rate can be reduced by ca. 40 %. Separate outlets are present at the inlet box for the normal chlorine gas production and the weak chlorine gas produced during start-up. The graphite catalyst in the vertical decomposer is activated with molybdenum.

5.2.3. Olin – Mathieson Cell

The special feature of the Olin – Mathieson cell lies in the system of mounting and adjusting the anodes. Above each row of anode rods, a U-shaped copper or aluminum bus bar also serves to support the anode lifting gear. The anode rods are bolted to the U-shaped bus bar. The anodes are adjusted as a group, either manually or by a remote computer with the remote computerized anode adjuster (RCAA) system. The currents are measured independently of the cell potentials by means of reed contacts [89].

5.2.4. Solvay Cell

The bus bars in the Solvay cells are made primarily of aluminum. Above the cells is a cover that also serves as a convenient walkway, giving access to the anode rods. The titanium anodes are specially coated and are automatically adjusted by computer. The tall vertical decomposers are located under the cells.

5.3. Operation

The aspects of the operation of mercury cells that typically differ from those of the other processes are the brine circulation system, the cell room, treatment of the products, measurement and control, and reduction of mercury emissions.

5.3.1. Brine System

A typical brine circulation system for the mercury cell process is shown in Figure 21. In the cells the sodium chloride concentration of the brine is reduced by 35 – 60 g/L to 260 – 280 g/L

Figure 21. Schematic diagram of a brine circulation system in the mercury cell process

Figure 22. Cell room: Uhde mercury cells

at 70 – 85 °C. To avoid mercury emissions into the air, the resaturators are generally closed vessels. The mercury cathode is very sensitive to poisoning by heavy metals; therefore, a test [90] has been developed that allows rapid determination of the suitability of any particular salt or brine.

5.3.2. Cell Room

The cells are usually situated in a building (Fig. 22), although sometimes they are erected in open air (Fig. 23). Figure 24 shows a bird's eye view, and Figure 25 shows a cross section of cell room. The cells are arranged parallel to each other so that bus bars and supply lines are kept short. The cells stand on supporting structures and are insulated to prevent shorting to the earth. The transformer and rectifiers are situated at one end of the room, and the cell service and repair area is at the opposite end. Ancillary equipment is installed near the cell room in a spillage containment area.

Figure 23. Open-air cell room: De Nora cells

Cell floors, gangways, and spillage containment areas are constructed with smooth, sloping floors so that any mercury can be easily recovered or wash water can be conveniently collected for treatment. The supply pipes run under the cells and are connected to them by flexible, insulating connections. The heat given off by the cells and the decomposers is removed by a ventilation system.

The plant is operated with continuous 24 h/d supervision and control. An additional day-shift team carries out anode changes, repairs, and cleaning.

Occupational Health. Anyone working in the cell area must undergo regular health checks. Euro Chlor has prepared a Code of Practice "Control of Worker Exposure to Mercury in the Chlor-Alkali Industry" [91]. The U.S. Chlorine Institute has released guidelines "Medical Surveillance and Hygiene Monitoring Practices of Worker Exposure to Mercury in the Chlor-Alkali Industry" [92]. The U.S. Environmental Protection Agency has established 18 rules re-

lating to cleanliness of the cell room [93]. Adherence to these rules eliminates any danger to the health of personnel caused by mercury. The maximum allowable concentration or threshold limit value (TLV) of mercury in the atmosphere in Western Europe and in the United States is between 0.025 and 0.100 mg/m^3.

5.3.3. Treatment of the Products

Chlorine. See Chapter 11.

Hydrogen. The treatment of the hydrogen gas leaving the decomposer is described in Chapter 4. It must pass special equipment for the removal of the traces of mercury before it is used (see page 25).

Sodium Hydroxide Solution. The great advantage of the mercury cell process is that very pure sodium hydroxide solution is produced (see Table 20) at a suitable concentration. The chloride content is only 5 – 50 mg/kg.

Sodium hydroxide from the decomposer usually has a concentration of 50 % and a temperature of 80 – 120 °C. It passes through rubber-lined steel pipe work to nickel or Incoloy coolers, where it is cooled to 40 – 60 °C. Any particles of graphite from the decomposer or traces of mercury are effectively removed by centrifuges, candle filters, or precoated leaf filters (Fig. 26).

Figure 26. Processing of sodium hydroxide solution from the amalgam decomposer
a) Vertical decomposer; b) Collection main; c) Collecting tank; d) Pump; e) Cooler; f) Mercury removal filter

The freezing-point and boiling-point curves of sodium hydroxide solutions are shown in Figure 27. The phases separating from the solution, i.e., ice, hydrates, and NaOH, are indicated along the freezing-point curve. Sodium hydroxide is supplied to consumers as aqueous solution, solid block, flakes, prills, or powder. For the processes involved and for uses, see → Sodium Hydroxide.

Figure 27. Freezing and boiling point curves of sodium hydroxide solutions

5.3.4. Measurement

The condition of the brine, the cells, and the products must be continuously and carefully monitored, since even small deviations from the correct conditions can increase the hydrogen concentration in the chlorine. The measuring operations are mostly automatic: critical limits are chosen and if these limits are exceeded, alarms are set off.

Cell Operating Conditions. The sodium concentration in the amalgam is determined at the cell inlet (max. 0.05 wt %) and outlet (max. 0.45 wt %).

A 20-g sample of the amalgam is reacted with 30 wt % aqueous sulfuric acid in an absorption pipette. The evolution of 1 cm^3 of gas corresponds to 0.01 wt % Na.

A portable analytical and recording apparatus is available that works electrochemically [94].

If the mercury pump stops, the steel cathode base of the cell is exposed to electrolyte, and hydrogen evolves to form an explosive mixture with the chlorine in the cell.

Failure of the mercury pump or mercury flow automatically short-circuits the cell. Mercury flow failure is detected by monitoring the mercury level at the lowest part of the mercury circulation system or in the inlet box, by direct flow measurement [95], or by loss of pressure at the pump delivery.

The motors for the mercury pumps, the chlorine absorption plant, and the most vital control equipment are all provided with an emergency power supply, ensuring safe shutdown of the plant if a power failure occurs. The installation is protected by a complex system of interlocks so that failure of important equipment, such as the chlorine compressor, shuts down the rectifiers.

A large number of systems have been developed for the protection of cells from short circuits. Titanium anodes are destroyed by short circuits and must be raised before any contact with the amalgam takes place.

The operation of the monitoring system depends on magnetic-field current measurement for individual anodes [89, 96, 97] or on shunt measurement of the supply bus bars [98]. Monitoring is achieved by comparison of the anode – cathode voltage of different cell sections [99] or by following the conductivity of the brine in the electrode gap [100].

The signals from the instruments are fed into central computers or local microprocessors at each cell [101] that control the anode lifting gear. The mercury inventory in each cell may be measured by a radioactive tracer technique once a year without affecting cell operation [102].

Products. The concentration of the sodium hydroxide solution is determined from its density, and the purity its checked by titration to determine hydroxide, carbonate, and chloride contents. The purity of the water for the decomposer is determined from its conductivity.

The oxygen content of the hydrogen gas is determined from the magnetic susceptibility, oxygen being paramagnetic.

5.3.5. Mercury Emissions (→ Mercury, Mercury Alloys, and Mercury Compounds, Chap. 5)

Any chlor-alkali plant up to modern technical standards is not a hazard to the environment. The residual emissions to water and air are ecologically acceptable. The mercury in the electrolytic cells circulates in a closed system. All materials that come into contact with the mercury – equipment, products, auxiliary chemicals, wash water, waste gases, other waste materials – may become contaminated with mercury, and must be treated before release to the environment or must be safely deposited. For the exact measurement of these trace amounts and for control of the effectiveness of the measures to reduce the emissions, analytical methods have been developed with sensitivities in the microgram region [103].

Many countries have set legal limits on emissions in waste air and water. The limits on the products of a chlor-alkali plant may depend on their end use, e.g., drinking water treatment or food processing. The sources of contamination are listed, and means of reducing them are described: Mercury cells are sealed vessels, and the products are conveyed in closed pipes. The cell rooms must have smooth joint-free floors with easily cleaned drainage surfaces and irrigated collection gutters (see Fig. 25). Spilled mercury is immediately washed away with water into collecting tanks or sucked up with a vacuum system.

Control of mercury loss is only possible if the mercury content of all the cells is known exactly. The gravimetric and volumetric methods formerly used were cumbersome and led to additional mercury emissions, disadvantages that are avoided by a radioactive tracer method.

Mercury in Products. Hot, moist *chlorine* leaving the cell contains small amounts of mercuric chloride. This is almost completely washed out in the subsequent cooling process and may be fed back into the brine with the condensate. In the cooled and dried chlorine gas, there are only minute traces of mercury: 0.001 – 0.01 mg/kg.

The equilibrium mercury concentration in *hydrogen gas* is a function of temperature and pressure. The mercury concentration (mg of Hg per m^3 of H_2 at 101.325 MPa) increases rapidly with temperature:

t, °C	0	20	40	60	80	100
c, mg/m^3	2.36	14.1	66.1	255	836	2404

Subjecting the hydrogen gas to pressure lowers the mercury content of the resulting prod-

uct gas at atmospheric pressure. For example, at 5 °C

$$c_{Hg}\, p = 0.37\ \text{Pa kg m}^{-3}$$

c_{Hg} = concentration of mercury in hydrogen gas at atmospheric pressure, mg of Hg per m^3 of H_2

p = pressure to which the hydrogen gas is subjected, MPa

When the mixture is cooled to 2 – 3 °C, the mercury concentration is reduced to ca. 3 mg/m^3 at standard pressure. This mercury content can be reduced by compressing and further cooling, adding chlorine to form mercurous chloride (calomel), which is collected on rock salt or similar material in a packed column, washing with solutions containing active chlorine, or by adsorption on activated carbon impregnated with sulfur or sulfuric acid, leaving a mercury concentration in hydrogen of 0.002 – 0.03 mg/m^3. The highest purity can be achieved by adsorption on copper/aluminum oxide or silver/zinc oxide, < 0.001 mg/m^3.

Centrifugation or filtration in candle filters or in disk filters precoated with charcoal gives *sodium hydroxide solutions* containing mercury concentrations of < 0.05 ppm (mg/kg of 50 % caustic soda).

The circulating brine contains mercury concentrations of 2 – 20 mg/L. Mercury emissions from the brine system can occur through losses of brine into the wastewater, by brine vaporization in the resaturators, or by disposal of the residues from the brine purification filter. These emissions are minimal at a chlorine concentration < 30 mg/L, giving a redox potential > 500 mV vs. NHE. Under these conditions mercury remains dissolved in the brine as a mercury chloride complex even if the brine is alkaline.

Mercury in Wastewater. Mercury-containing wastewater has several sources:

1) The process, e.g., condensate and wash liquor from treatment of chlorine, hydrogen, and brine; stuffing-box rinse water from pumps and blowers; brine leakages; ion-exchange eluate from process-water treatment
2) Cell cleaning operations
3) Cleaning of floors, tanks, pipes, and dismantled apparatus

The amount of wastewater can be reduced by separately disposing of the cooling water and process water and by feeding the condensate back into the brine, provided the water balance allows this. A wastewater rate of 0.3 – 1.0 m^3 per tonne of chlorine is achievable.

There are various methods of making wastewater suitable for discharge:

1) Chemical removal of mercury by reducing any compounds to the metal with hydrazine or sodium borohydride or by precipitating mercuric sulfide with thiourea or sodium sulfide. The mercury metal or sulfide is then filtered off.
2) Oxidation of the mercury by chlorine, hypochlorite, or hydrogen peroxide and adsorption on an ion-exchange medium. Elutriation is done with hydrochloric acid, which is then used to acidify the brine [104].

The Clean Water Act of 1972 (United States) demands the use of the "best available technology economically achievable." Since 1982 each plant has been limited to a maximum of 0.1 g of Hg per tonne of chlorine averaged over 30 d measured at the outlet of the wastewater treatment plant.

In Western Europe, an EC directive has been issued on the subject of the mercury content of wastewater from chlor-alkali plants, following various earlier agreements such as the Rhine protection agreement, the EC guidelines concerning the protection of natural waters, and the Paris Convention [105]. This directive requires plants with circulating brine systems to have a limit of 1.0 g of Hg per tonne of chlorine produced.

Mercury in Process Air. Air from the process, for example, the cell end box ventilation system, vents from liquid collection tanks (caustic, wastewater), from the vacuum cleaning system, or from the distillation unit for mercury-contaminated wastes can be treated to remove mercury by the methods used for hydrogen.

Ventilation of the Cell Room. The heat produced during electrolysis requires that the air must be changed 10 – 25 times per hour, depending on the type of building. Mercury spillage can

occur during essential operations involving cells or decomposers, for example, opening the cells for anode changing or cleaning, assembling or dismantling equipment, or replacing defective pipes. Spillage leads to small losses in the exhaust air owing to the vapor pressure of mercury. In addition, products that contain mercury, such as the sodium hydroxide solution, hydrogen, or process waste air, can escape via faulty seals in pipes and equipment, leading to emissions. Closed cell construction and special care in handling mercury, i.e., good housekeeping, by adhering to the EPA rules or the Code of Practice "Mercury Housekeeping" [106], keep the mercury concentrations and, hence, emissions below the allowable work place concentrations (MAK and TLV) [107].

Purification of large volumes of waste air containing mercury in very low concentrations is not effective. In the United States, the upper limit for the emission of mercury in process waste air and hydrogen is 1 kg per day per facility, and for ventilation air it is 1.3 kg per day per facility [18, p. 372]. In Western Europe the Parcom Decision 90/3 [108] requires a standard of 2 g Hg/t of chlorine capacity for emissions to the atmosphere from existing plants.

Mercury in Residues. Mercury-containing residues include brine filter slurry, spent decomposer catalyst, discarded cell components, residues from the purification of products, waste material from rinsing media, adsorption materials, ion-exchange media, etc. Mercury can be recovered from these materials by distillation in closed retorts. The residues after distillation must be disposed at special sites. Mercury in safely deposited wastes is not considered an emission to the environment.

Summary. The continued efforts of all producers have led to a steady decrease in mercury emissions over the years; for example, in Western Europe from 16 g in 1978 to 2 g Hg per tonne of chlorine capacity in 1996, as shown in Figure 28 [109]. With this low emission level, the contribution of the chlor-alkali industry to the total natural and anthropogenic mercury emissions is less than 0.1 % [111]. Euro Chlor is developing a BAT (best available techniques) for reducing mercury emissions from existing mercury-based plants, the application of which will ensure that in 2007 no plant emits more than 1.5 g Hg per tonne of chlorine capacity to air, water, and products [109].

Figure 28. Mercury emissions from the European chlor-alkali industry

6. Diaphragm Process

The commercial production of chlorine by electrolytic processes began in Europe and the United States in the 1890s. Early cells of the bell-jar type had no diaphragm and relied on the flow of anolyte toward the cathode to prevent the hydroxide ion from back-migrating toward the anode. This method had limited capacity because gas evolution caused mixing and loss of efficiency. The Griesheim cell, another early design, used porous cement as the diaphragm.

E. A. Le Sueur is credited with the design of a cell incorporating a percolating asbestos diaphragm, which is the basis for all diaphragm chlor-alkali cells currently in use. When brine is caused to flow into the anolyte and subsequently through the diaphragm into the catholyte, continuous operation with much improved efficiency is obtained. This Le Sueur cell, and the similar Billiter cell developed in Germany, incorporated a horizontal asbestos sheet as the diaphragm. During the 1920s, the Billiter cell became the most widely used cell in the world; a few are still in operation.

Following the invention of synthetic graphite, numerous cells were developed. These fall into three basic types:

1) Rectangular vertical electrode cells

2) Cylindrical vertical electrode cells
3) The vertical electrode bipolar filter press cell developed by Dow Chemical

In 1913, C. W. Marsh developed a cell with finger cathodes and side-entering anodes and cathodes, which greatly increase the electrode area per unit of floor space. About 1928, Kenneth Stewart of Hooker Chemical (now Occidental Chemical Co.) developed a method of depositing asbestos fibers onto the cathode by immersing the cathode in a slurry of asbestos fibers and applying a vacuum. All significant installations of diaphragm cells currently in operation are derived from that development [2].

All diaphragm cells produce cell liquor that contains ca. 11 wt % caustic soda and 18 wt % sodium chloride. To market the caustic soda, its concentration must be increased to 50 %. During the evaporation and cooling processes, the salt becomes less soluble in the stronger caustic, and at 50 % NaOH the NaCl concentration is ca. 1 %.

6.1. Principles

The principles needed to understand the efficient operation of the diaphragm process involve the current efficiency, cell voltage, power consumption, and optimization of the operating conditions [112, 113].

The reaction at the positively charged anode is the same for all three chlor-alkali processes

$$2\,Cl^- \rightarrow Cl_2 + 2e^-$$

The reaction at the negatively charged cathode of the diaphragm cell is

$$2\,H_2O + 2\,e^- \rightarrow H_2 + 2\,OH^-$$

Figure 29 is a cutaway view of a diaphragm cell that shows the orientation of the various parts of the cell and the various reactions that take place. Figure 29 also shows the location of the diaphragm, which is deposited on the outside of the cathode screen and which separates the cell into two compartments, one containing the anodes and one containing the cathode. The sodium chloride solution (brine) enters the anode compartment and completely covers the anodes and the cathode tubes or fingers. The chlorine leaves the cell through an outlet in the cell head. The anolyte flows through the diaphragm into the cathode compartment because of the difference in liquid level between the two compartments. The catholyte is a solution of sodium chloride and sodium hydroxide because a portion of the water is converted to hydroxide at the cathode. The hydrogen produced at the same time leaves the cell through an outlet on the cathode. The solution of sodium chloride and sodium hydroxide overflows the cell through a level control pipe on the cathode, and is then commonly called cell liquor.

Figure 29. Basic chemical reactions within the cell
a) Anode compartment; b) Cathode compartment; c) Deposited diaphragm on cathode tubes, rims, and end screens

Current Efficiency. Current efficiency is defined as the amount of product actually produced divided by the amount of product that theoretically should have been produced on the basis of the amount of direct-current electrical energy input. The current efficiency is never 100 % because of side reactions. The efficiency of a diaphragm cell is usually based on the chlorine production.

The side reactions that lower the efficiency are a result of chlorine that enters the catholyte compartment or of hydroxide ions that enter the anolyte compartment. The amount of chlorine that enters the catholyte compartment is small.

The majority of the efficiency losses in a diaphragm cell are due to migration of hydroxide ions from the catholyte through the diaphragm and into the anolyte. This back migration takes place because the negatively charged hydroxide ions are attracted to the positively charged anodes and because of the hydroxide ion concentration gradient across the diaphragm. This migration of hydroxide ions through the diaphragm is in equilibrium with the opposing flow of brine through the diaphragm.

Three factors control the migration of the hydroxide ions into the anolyte:

1) Concentrations of hydroxide and chloride ions at the cathode side of the diaphragm
2) Flow rate of brine through the diaphragm
3) Condition of the diaphragm

These three factors in dynamic equilibrium determine the efficiency of the cell.

Factor 1. The higher the concentration of hydroxide ions in the catholyte, the larger the concentration gradient across the diaphragm, and the higher the probability of hydroxide ions crossing through the diaphragm. As a result, changing cell liquor strength strongly affects cell efficiency. The concentration of chloride ions in the catholyte also affects cell efficiency because some of the chloride ions migrate in place of hydroxide ions.

Factor 2. Decreasing brine flow rate to a cell increases the conversion of sodium chloride to sodium hydroxide and raises the hydroxide concentration in the catholyte because of reduced overflow from the cell. The decreased flow rate of brine through the diaphragm allows increased migration of hydroxide ions into the anolyte. These factors decrease cell efficiency.

Factor 3. The condition of the diaphragm is extremely important. Nonuniformity in the diaphragm results in high flow rates of brine through thin or loosely compacted areas and low flow rates through thick or compacted areas. In the areas where there is a low brine flow rate, back migration of hydroxide is increased.

The degree of inefficiency in a cell is indicated by the two products of the side reactions, oxygen in the chlorine and sodium chlorate in the cell liquor. Oxygen in the chlorine gas is the result of hydroxide ions that migrate through the diaphragm into the anolyte, where they are oxidized:

$$2\,OH^- \rightarrow 1/2\,O_2 + H_2O + 2\,e^-$$

Sodium chlorate in the cell liquor is a result of hydroxide ions that migrate through the diaphragm into the anolyte and react with chlorine before reaching the anode:

$$3\,Cl_2 + 6\,NaOH \rightarrow NaClO_3 + 5\,NaCl + 3\,H_2O$$

Equations. The simplest equations for calculating cell efficiency are based on the masses of products produced per unit of electrical input. Theoretically, 1.492 kg of sodium hydroxide and 1.323 kg of chlorine are produced per kiloampere-hour. It then follows that

$$\text{Cathode efficiency},\% = (\text{kg of NaOH} \times 100)\,/\,(Q \times 1.492 \times \text{the number of cells})$$

$$\text{Anode efficiency},\% = (\text{kg of } Cl_2 \times 100)\,/\,(Q \times 1.324 \times \text{the number of cells})$$

where Q is the quantity of electricity in kA h

Unfortunately, the production of a single cell cannot be measured with sufficient accuracy to give meaningful results. To get around this problem, the chlorine industry uses an equation based on the analysis of the chlorine gas, the cell liquor, and the anolyte:

$$\%CE = [\%Cl_2 \times 100]\,/\,[\%Cl_2 + 2\,(\%O_2) + (\%Cl_2 \times anox \times F)\,/\,c_{NaOH}]$$

where

% CE =	anode current efficiency, %
% Cl_2 =	percent chlorine in cell gas (air free)
% O_2 =	percent oxygen in cell gas (air free)
anox =	oxidizing power of anolyte expressed as grams of $NaClO_3$ per liter
c_{NaOH} =	NaOH concentration in the cell liquor, g/L
F =	conversion factor

Table 6. Typical voltage distribution [a]

Component voltages, V	Current density, kA/m^2				
	1.24	1.55	1.86	2.17	2.48
Anode potential [b]	1.30	1.30	1.30	1.30	1.31
Cathode potential [b]	1.12	1.13	1.15	1.16	1.17
Structure loss [c]	0.11	0.14	0.17	0.20	0.22
Brine loss	0.11	0.15	0.19	0.23	0.27
Diaphragm loss	0.24	0.31	0.36	0.41	0.47
Intercell bus	0.02	0.02	0.03	0.03	0.03
Total	*2.90*	*3.05*	*3.20*	*3.33*	*3.47*

[a] OxyTech MDC-55 cell with Modified Diaphragm and expandable anodes. Conditions: anolyte temperature 93 °C, anolyte NaCl concentration 250 g/L, catholyte NaOH concentration 130 g/L.
[b] Potential vs. NHE.
[c] Includes anode base, anodes, cathode, cathode screens, copper end connectors, and copper side plates.

The denominator is the amount of chlorine produced plus the amount of chlorine consumed in the side reactions. This is equivalent to the amount of chlorine that could have been produced theoretically from the input of current. The conversion factor F is the product of a volume factor, an electric field factor, and a stoichiometric factor. In practice, it is a function of cell liquor strength.

The *SIX equation* is a practical alternative to the previous equation and is often used with computers linked to a gas chromatograph and an automated cell liquor analyzer. The SIX equation is

$$\%\mathrm{CE} = [\%\mathrm{Cl_2} \times 100] \,/\, \left[\%\mathrm{Cl_2} + 2\,(\%\mathrm{O_2}) + \left(\%\mathrm{Cl_2} \times 6 \times c_{\mathrm{NaClO_3}}\right) / c_{\mathrm{NaOH}}\right]$$

This equation also accounts for chlorine lost to the anolyte. However, it approximates the oxidizing potential of the anolyte with the concentration of chlorate in the cell liquor and assumes a fixed conversion factor from anolyte concentration to catholyte, namely *SIX*. The SIX equation approximates the standard equation within 0.5 %.

Cell Voltage. The voltage of a cell is the sum of five component voltages: anode potential, cathode potential, cell structure voltage drop, diaphragm voltage drop, and anolyte – catholyte voltage drop. The anode and cathode potentials are sums of the reversible voltages, which are the thermodynamic minimum amounts of work to cause the reactions to take place, and the overpotentials, which are the additional voltages required for nonreversible kinetics. The cell structure voltage drop includes the voltage losses in the cathode, anodes, intercell bus, and all other connectors in the cell. The sum of the diaphragm voltage drop and the anolyte – catholyte (brine) voltage drop is the potential between the electrodes. All of these voltages are functions of current density. Table 6 shows how cell voltage is strongly affected by cell current. Cell temperature, feed brine NaCl concentration, and the cell liquor NaOH concentration also affect cell voltage (Table 7), because they affect the conductivity of the solutions between the electrodes. Table 7 clearly shows that current density is the most important factor.

Table 7. Factors affecting cell voltage: the change in cell voltage ΔU_{cell} divided by the change in four important cell factors

Factor	Modified cell *	Standard cell *
ΔU_{cell}/change in current density J, mV m^2 kA^{-1}	450	450
ΔU_{cell}/change in cell temperature t_{cell}, mV/°C	−7.7	−10.1
ΔU_{cell}/change in brine concentration c_{NaCl}, mV L g^{-1}	−0.7	−1.8
ΔU_{cell}/change in cell liquor concentration c_{NaOH}, mV L g^{-1}	0.26	0.6

* OxyTech MDC-55 cell. The modified cell is outfitted with the Modified Diaphragm and expandable anodes, whereas the standard cell is outfitted with the standard asbestos diaphragm and the standard DSA anode. Conditions: anolyte temperature of 93 °C, anolyte NaCl concentration of 250 g/L, and catholyte NaOH concentration of 130 g/L.

Excessive brine impurities or other severe operating problems can adversely affect the voltage of the cell.

Power Consumption. The power consumption of a cell, kWh per tonne of Cl_2, may be calculated from the cell voltage by the following equation:

$$\text{Power consumption} = U_{\text{cell}} \times 756/\varepsilon$$

where

U_{cell} = cell voltage, V

ε = cell efficiency expressed as a decimal

Optimization. The relationships described in the preceding paragraphs can be used to determine the optimum economical cell operating conditions. The optimizations that must be considered are the following:

1) Higher cell liquor caustic strength and lower steam usage in caustic evaporation versus lower cell efficiency and higher power consumption
2) Lower current density, lower voltage, and lower power consumption versus additional cells and higher capital costs
3) Lower feed brine temperature, thus decreased steam usage for brine heating, versus higher cell voltage, lower efficiency, and higher power consumption
4) High brine pH and reduced acidification costs versus lower chlorine efficiency, higher power consumption, and lower product purity

Each diaphragm cell chlorine plant must determine its own optimum conditions for the most economical operations.

6.2. Diaphragm Cells

Electrolyzers for the production of chlorine and sodium hydroxide, including both diaphragm and membrane cells, are classified as either monopolar or bipolar. The designation does not refer to the electrochemical reactions that take place, which of course require two poles or electrodes for all cells, but to the electrolyzer construction or assembly. There are many more chlor-alkali production facilities with monopolar cells than with bipolar cells.

Bipolar electrolyzers have unit assemblies of the anode of one cell unit directly connected to the cathode of the next cell unit, thus minimizing intercell voltage loss. These units are assembled in series like a filter press, and therefore, the voltage of an electrolyzer is the sum of the individual cell voltages created by the anode of one unit, a diaphragm, and the cathode of the next unit. Bipolar electrolyzers have high voltages and relatively low amperage; therefore, the cost of electrical rectification is lower per unit of production capacity. Bipolar electrolyzers either must be installed in a large number of electrical circuits or be designed with very large individual cell components. Developers have chosen the option for large components.

Dow Chemical was the only early developer to have chlorine production needs large enough to consider the bipolar option [2]. Later, following the development of the DSA anode, PPG Industries and Oronzio De Nora Impianti Elettrochimici designed, and PPG Industries installed Glanor bipolar electrolyzers in a large complex at Lake Charles, Louisiana [12].

The *monopolar* electrolyzer is assembled so that the anodes and cathodes are in parallel. Therefore, the potential difference of all cells in the electrolyzer is the same, and the amperage at any particular current density only depends on the electrode surface area. A monopolar electrolyzer has low voltage and high amperage. The highest amperage rating of the most common modern monopolar cells is ca. 150 kA. Because a monopolar electrolyzer has a voltage of only 3 – 4 V, circuits of up to 200 electrolyzers have been constructed, producing 900 t of chlorine per day.

Diaphragms. The earliest asbestos diaphragms were made of sheets of asbestos paper. Asbestos was chosen because of its good chemical stability and its ion-exchange properties. Asbestos has been relatively inexpensive, since it is a relatively abundant natural material that was already being mined and processed for other industrial purposes, such as insulation.

The deposited asbestos diaphragm developed by Hooker Chemical in 1928 was the most common diaphragm until 1971, when what is now OxyTech Systems developed the Modified Diaphragm. The Modified Diaphragm is a mixture of asbestos and a fibrous fluorocarbon polymer [114]. The polymer stabilizes the asbestos,

which in itself lowers cell voltage and also allows for the use of the expandable DSA anode [115]. In its various formulations, the Modified Diaphragm is the most common diaphragm. The Modified Diaphragm still contains a minimum of 75 % asbestos.

Environmental concern over the use of asbestos has increased. France, Saudi Arabia, and Norway have banned the use of asbestos as a separator in chlorine cells. These nations allowed local chlorine producers several years to install non-asbestos replacement separators in existing diaphragm cells or to replace the cells themselves with membrane cells. Other European nations issue permits for the continued use of asbestos until an agreed upon BAT (best available technology) for diaphragm cells is established.

There is also concern in the chlor-alkali-industry for the future supply of asbestos, as most of the North American mines producing the grades of asbestos previously used for chlorine cell diaphragms have closed. At present the most common source of asbestos for chlorine cell diaphragms is Zimbabwe. In addition asbestos disposal costs and regulation have continued to increase. All of theses factors have led the chlor-alkali industry to consider non-asbestos diaphragm technology. Three non-asbestos diaphragm systems are commercially available today.

Chloralp Asbestos-Free Technology. Chloralp, a joint venture of Rhône-Poulenc and La Roche, has developed an asbestos-free diaphragm based on the built-in activation concept. The Chloralp separator is made of two vacuum-deposited layers:

1) The first layer, known as the precathode, is a conductive mat of carbon fibers, containing an electrocatalytic powder to decrease the cathode overpotential
2) The second layer is the diaphragm itself, in which PTFE and inorganic materials have replaced asbestos

The cathodic activation provides energy savings from 50 to 150 mV, depending on the plant operating conditions, and the catalyst content in the mat. Other benefits from the precathode are electrocatalytic destruction of chlorates and lower hydrogen contents in the chlorine after plant shutdowns. The diagraphm is deposited on the precathode by standard vacuum techniques. To control the diaphragm porosity, a pore-forming agent is incorporated in the slurry. Optimized porosity leads to lower cell voltage and higher current efficiency.

The technology is currently evaluated on OxyTech HC-3B electrolyzers at the Chloralp Pont-De-Claix facility. Compared to polymer-modified diaphragms, Chloralp asbestos-free separators provide a 150 mV saving on voltage and a 2 % improvement in current efficiency. Combined benefits from the precathode and the diaphragm, as well as an extended lifetime, could lead in the near future to full conversion of the 240 000 t/a Pont-De-Claix plant.

OxyTech Polyramix Diaphragm. OxyTech Systems has developed and commercialized a synthetic non-asbestos diaphragm called the Polyramix diaphragm. The Polyramix fiber is composed of a PTFE [poly(tetraflouroethylene)] fibrid base with zirconium oxide ceramic particles embedded in and on the fiber. The Polyramix diaphragm is vacuum deposited onto the cathode and then baked in an oven to fuse the fibers together. The process is very similar to OxyTech's widely used Modified Diaphragms. The Vulcan Chemicals plant in Geismar Louisiana was fully converted to the use of Polyramix diaphragms in 1993. Most major diaphragm cell chlorine plants have operated from 2 to 40 Polyramix diaphragm cells. The longest life cell with a Polyramix diaphragms has been in operation for over ten years [116].

PPG Industries Tephram Diaphragm. PPG Industries has developed and commercialized the Tephram diaphragm as its entry into the non-asbestos diaphragm market. Major goals of PPG's non-asbestos program were to produce a diaphragm that deposited and operated similarly to asbestos, with longer diaphragm life and lower power consumption. This technology utilized vacuum deposition to produce a base diaphragm composed of PTFE and a topcoat from a slurry of inorganic particulate materials. Dopants are priodically added to the anolyte during cell operation to adjust the diaphragm permeability to maintain or improve cell operation. This diaphragm has been successfully tested of the major monopolar cell technologies, as well

as on PPG's Glanor bipolar cells. An active program is in place to operate diaphragms on a trial basis at various producer sites, allowing for site-specific evaluation of the overall economics of the diaphragm.

6.2.1. Dow Cell [2, 117, 118]

The Dow Chemical Company is the largest chlor-alkali producer, accounting for one-third of the U.S. production and one-fifth of the world capacity. Because Dow's production capacity is large and concentrated in a few sites, Dow's cell development followed a different path than other chlor-alkali technology developers. Dow uses its own cell design of the filter press *bipolar* type. Dow has operated filter press cells for over 90 years. Dow cell development occurred in several stages, characterized by simple rugged construction and relatively inexpensive materials.

Figure 30. Dow diaphragm cell
A) Six-cell series
B) Internal cell parts: a) Cathode element; b) Cathode pocket elements; c) Copper spring clips; d) Perforated steel backplate; e) Brine inlet; f) Chlorine outlets; g) Copper backplate; h) Titanium backplate; i) Anode element

The cell employs vertical DSA coated titanium anodes, vertical cathodes of woven wire mesh bolted to a perforated steel backplate, and a vacuum-deposited modified asbestos diaphragm. A single bipolar element may have 100 m^2 of both anode and cathode active area. The anode of one element is connected to the cathode of the next by copper spring clips. This connection is immersed in the cell liquor during operation. Figures 30 B and 31 show these internal cell parts.

Figure 31. Dow diaphragm cell, section view
a) Perforated steel backplate; b) Cathode pocket; c) Asbestos diaphragm; d) DSA anode; e) Copper backplate; f) Titanium backplate

Dow operates at lower current densities than others in the chlor-alkali industry. The electrolyzers are normally operated with 50 or more cells in one unit or series. One electrical circuit may consist of only two of these electrolyzers. Figure 30 A shows a view of six electrolytic cells.

Treated saturated brine is fed to the anolyte compartment, where it percolates through the diaphragm into the catholyte chamber. The percolation rate is controlled by maintaining a level of anolyte to establish a positive, adjustable hy-

drostatic head. The optimum rate of brine flow usually results in the decomposition of ca. 50 % of the incoming NaCl, so that the cell liquor is a solution containing 8 – 12 wt % NaOH and 12 – 18 wt % NaCl.

The Dow diaphragm cell, optimized for low current density, consumes less electrical energy per unit of production than the rest of the industry. The cell voltage at these low current densities is only 300 – 400 mV above the decomposition potential of the cell. However, Dow has a larger investment in the electrolyzers, especially anodes.

The electrolyzers are operated at ca. 80 °C, lower than the 95 °C typical of other types of cells. This lower operating temperature allows cell construction with less expensive materials, such as vinyl ester resins and other plastics [117]. Operating data have not been published.

6.2.2. Glanor Electrolyzer [12, 119 – 121]

Glanor *bipolar* electrolyzers are a joint development of PPG Industries and Oronzio De Nora Impianti Elettrochimici S.p.A. The Glanor electrolyzer consists of several bipolar cells clamped between two end electrode assemblies by means of tie rods, thereby forming a filter press type electrolyzer (Fig. 32). The electrolyzer is equipped with DSA titanium anodes. Each electrolyzer normally consists of 11 or 12 cells. A lower number of cells can, however, be assembled in one electrolyzer. The Glanor electrolyzer was especially designed for large chlor-alkali plants.

The current is fed into the electrolyzer by means of anodic and cathodic end elements. The anodic compartment of each cell is connected to an independent brine feed tank by means of flanged connections.

Chlorine gas leaves each cell from the top through the brine feed tank and then passes to the cell room collection system. Hydrogen gas leaves from the top of the cathodic compartment of each cell, while the catholyte liquor leaves from the bottom through an adjustable level connection.

Figure 32. Glanor bipolar electrolyzer
a) Disengaging tank; b) Chlorine outlet; c) Hydrogen outlet; d) Bipolar element; e) Brine inlet; f) Cell liquor trough; g) Cell liquor outlet

Figure 33. Glanor bipolar electrolyzer type V-1144

The V-1144 electrolyzer (Fig. 33) was the first commercial unit, and eight plants utilize this model. The second generation is the V-1161 electrolyzer, which employs Modified Diaphragms, narrower electrode gaps, lower current density, and DSA anodes to achieve lower power consumption than the V-1144 electrolyzer.

The operating characteristics of the Glanor electrolyzers are shown in Table 8.

6.2.3. OxyTech "Hooker" Cells [2, 12, 122, 123]

The first commercialized deposited asbestos diaphragm cell was the Hooker type S-1 monopolar cell, introduced in 1929. The basic design featured vertical graphite anode plates connected to a copper bus bar and a cathode with woven steel wire cloth or perforated steel fingers between the anodes. The cathode held vacuum-deposited asbestos fiber diaphragms that separated the anode and cathode compartments. The cathode fingers did not extend completely across the cell, but left a central circulation space. In the following 40 years, a family of S series cells with similar characteristics evolved, with over 12 000 having been installed in licensed plants.

In 1973, a new H series of *monopolar* cells was introduced. They incorporated the use of DSA anodes, which had been developed and commercialized in the late 1960s. These cells have significant voltage savings over the S series, thus allowing increases in cell capacity without corresponding increases in rectification capacity. The H series also incorporate cathode tubes with both ends open, extending across the cell, as the circulation space requirement was satisfied by the change from solid graphite anodes to the open DSA anodes (Fig. 34).

6.2.4. HU Monopolar Cells [123]

The HU type cells were a joint development of Hooker (now OxyTech Systems) and Uhde. The HU-type electrolyzer (Fig. 35) is rectangular, not cubic, and is narrow in the direction of current flow, since anodes are arranged in a sin-

gle row. The cathode is long and narrow; consequently, the current density is lower through the cathode shell. The long, narrow cathode fabrication lends itself to closer anode–cathode tolerances and spacing. Copper on and around the cathode shell has been eliminated. Another advantage of the long, narrow design is shorter electrolysis current paths through the cell room, resulting in savings in piping and other materials. The HU-type cell incorporates a Modified Diaphragm.

A further novelty of the HU cell system is the design and arrangement of the bypass switch. The HU switch is installed underneath, not next to, the circuit of cells. This is accomplished by raising the cells from the floor, similar to mercury cells, creating a second operating floor. The interconnecting bus bars are flexible and are distributed over the entire length of the cell. The HU cell design incorporates a bus bar for each individual anode. This, as well as the elevation of the cell from the floor below, which allows access, enables connection of facilities for monitoring the current flowing through each anode. During operation of the bypass switch, connection is made for each individual anode, and no additional contact bus bars are required.

The HU-type cells are offered to cover 30–150 kA. All of the different cell types are equipped with cathodes and anodes of identical height and width. The only basic difference between the various cell models is the number of

elements and consequently the length of the cell (Table 10). Cell voltage and power consumption per tonne of chlorine, identical for all cell types, are shown in Table 11 for the specific current loads of 1.5 and 2.3 kA/m^2.

6.2.5. OxyTech MDC Cells [12, 124]

OxyTech Systems manufactures and licenses the MDC series of *monopolar* diaphragm cells (Fig. 36). The MDC cells feature woven steel wire cathode screen tubes open at both ends, which are welded into thick steel tube sheets at each end. The tubes, tube sheets, and the outer steel cathode shell form the catholyte chamber of the cell (Fig. 37). Copper is bonded, rather than welded, to the rectangular cathode shell on the two long sides parallel to the tube sheets. Copper connectors attached at the ends of the bonded copper side plates complete the encompassing of the cathode with copper. Anodes are connected to a copper patented cell base, which is protected from the anolyte by a rubber cover or a titanium base cover (TIBAC) [125]. Orientation of the cathode tubes is parallel to the cell circuit, the opposite of a Hooker-type cell. This arrangement accommodates thermal expansion of the cell and circuit without changing the anode-to-cathode alignment.

The combination of the Modified Diaphragm and expandable DSA anodes reduces power consumption by 10 – 15 % from that of regular asbestos diaphragms and standard, fixed DSA anodes [126]. Table 12 presents performance data for the two most common MDC cell sizes [124]. The OxyTech MDC-29 is shown in Fig. 38. The licensed chlorine capacity of OxyTech cells now exceeds 20 000 t/d.

6.3. Operation

The process description in this section is intended to provide an overview of typical diaphragm cell process areas. A general block diagram for a diaphragm cell facility is shown in Figure 9. Included on the drawing are many process areas that may be optional, depending on the design of the plant and its end products. The operation of a cell room may be broken down into six areas: the two incoming systems, brine and electrical; the cells; and the three outgoing systems, chlorine, hydrogen, and cell liquor. Some of these are essentially the same for all three chlor-alkali processes and are described in Chapter 4 — the brine system (general), the electrical system, and the hydrogen system. The treatment of the chlorine is the subject of Chapter 11. Only aspects that are reasonably specific to the diaphragm cell process are described in this section.

6.3.1. Brine System

Most commonly, diaphragm cells are supplied with well brine on a once-through basis. The treated well brine flows to the treated brine storage tanks, which usually have 12-h capacity. From there the brine is fed to the cell room. The

flow to each individual electrolyzer is controlled by a rotameter. If the flow of brine to the cells is suddenly disrupted by failure of the brine feed pump, the rectifiers automatically shut down since an inadequate supply of brine to the cells is potentially dangerous. The specifications for brine for diaphragm cells are given in Table 13.

A brine recovery lagoon is usually available to handle any major upsets in the brine system. Brine sludges or out-of-spec brine can be sent to the lagoon. Supernatant clear brine can be recovered from the lagoon.

In most cases, operation with acidic brine is preferred because of the reduced amount of side-reaction products in the chlorine and the cell liquor.

6.3.2. Cell Room

Typical cell rooms are shown in Figures 39 (bipolar cells) and 40 (monopolar cells).

Figure 38. OxyTech MDC-29 with the author (1971)

Figure 39. Cell room: bipolar PPG Industries/De Nora Glanor cells

A cell in normal operation requires little attention. The critical requirement is that the *brine flow rate* is sufficient to maintain an anolyte level above the cathode.

Table 13. Typical brine feed specifications for diaphragm cells

Parameter	Specification
NaCl	$\geqq$320 g/L
pH	2.5 – 3.5
Hardness ($Ca^{2+} + Mg^{2+}$)	<5 ppm
Magnesium	<0.4 ppm
Sodium sulfate (Na_2SO_4)	<5 g/L
Organics	<1 ppm
Manganese	<0.01 ppm
Barium	<0.01 ppm
Nickel	<0.1 ppm
Iron	<0.5 ppm
Silicon	<15 ppm
Cobalt	<0.02 ppm
Mercury	<1 ppm
Phosphate	<1 ppm

Figure 40. Cell room: monopolar OxyTech H-4 cells

Under no circumstances should a cell be operated with an inadequate or excessive anolyte level. Operation with the anolyte level not visible in a sight glass is unsafe. At least one operator should be in the cell room at all times. The cell room operator should inspect the anolyte level and brine flow to each cell at least once per hour. Any change in the anolyte level or brine flow rate should be investigated.

As the cell ages, the diaphragm will undergo changes in porosity because of the following:

1) Electrolysis effect
2) Brine impurities
3) Upsets in operation
4) Gradual wear of the diaphragm

A change in porosity may necessitate a change in brine flow rate. If the increase in porosity is severe, the cell may be replaced or doped with an asbestos slurry or inorganic salts.

Impurities in the brine often lead to decreased porosity. Decreased porosity can be offset to some extent by increasing the anolyte level and, if necessary, by lowering the catholyte level.

A cell operated with the anolyte level at the maximum value and the lowest catholyte level is called a sleeper. To gain additional diaphragm life after a cell has entered the sleeper position, the brine flow rate must be decreased below normal. This is not normally a recommended practice because current efficiencies of these cells are usually low.

For safe operation of diaphragm cells, the *header pressures* must be maintained at the proper values.

The chlorine header should be maintained at positive pressure to permit detection and correction of any chlorine piping leaks. The hydrogen header is also maintained at a positive pressure to avoid pulling air into the hydrogen, creating a potentially explosive mixture. The brine header pressure should be maintained to give the desired caustic concentration in the cell liquor. Normal practice is to adjust individual brine feed valves so that each cell receives the correct brine flow rate.

Load changes must be smooth to avoid fluctuations in the header pressures and detrimental effects on the diaphragms.

The brine feed rate to each cell should be increased to the new rate before circuit amperage is increased. The brine feed rate to each cell should be decreased immediately after amperage is decreased. During any period of operation when brine flow rates are being changed, extra attention should be given to the anolyte levels of the cells. Adjustment of the brine feed temperature may also be necessary when a load change occurs.

6.3.3. Diaphragm Aging

Of all the cell components, the diaphragm usually has the shortest life. The ability of a diaphragm to resist the back migration of hydroxide slowly becomes impaired with service life. The performance of the diaphragm deteriorates for the following reasons:

1) Chemical attack
2) Brine impurities
3) Unsteady operating conditions

The major reason for the deterioration is *chemical attack* on the asbestos by the alkaline catholyte and acidic anolyte. The rate of chemical attack can be minimized and diaphragm life maximized by careful operation of the cell. The most important situations to avoid are high concentrations of brine impurities and unsteady operating conditions. High *brine impurities* cause plugging of the diaphragm with insoluble hydroxides, which reduce the diaphragm's separation ability. The most common harmful impurities are calcium, magnesium, iron, nickel, silicates, aluminum, manganese, and barium.

Unsteady operation, such as electrical load changes, cell liquor strength changes, changes in brine concentration or pH, gas-pressure fluctuations, and shutdowns, change the pH of the various regions of the diaphragm, thus accelerating chemical attack on the asbestos. Diaphragm cell plant operators should strive to minimize these changes.

The real importance of the equations in Section 6.1 is as an aid in deciding when the diaphragms should be replaced.

6.3.4. Treatment of the Products

Chlorine. See Chapter 11.

Hydrogen. See Chapter 4.

Sodium Hydroxide Solution. The hydroxide produced at the cathode is associated with sodium ions and water to form a 10 – 12 wt % sodium hydroxide solution leaving the electrolytic cell. This cell liquor also contains 18 wt % unreacted sodium chloride.

Most large modern chlor-alkali plants have or will soon have an associated cogeneration power plant. In these facilities, the caustic evaporators are an important use for the byproduct steam.

Modern diaphragm cell plants use triple-effect evaporators and, in many cases, quadruple-effect evaporators.

Figure 42. Caustic purification system

Caustic Soda Evaporation. A flow diagram for a typical triple-effect caustic soda evaporator is shown in Figure 41. The evaporator is of the backward-feed design and concentrates 10–11.3 wt % NaOH cell liquor to 50 wt % NaOH. Liquor flows from the third to the second to the first effect and from the first effect to the liquor flash tank. A cyclone is used for each effect to utilize the pressure drop across the circulating pump to clarify the transfer liquor.

The salt precipitated in the liquor flash tank is isolated from the rest of the salt precipitated in the evaporator and used as seed crystals in the cooling system to help diminish coil scaling and supersaturation of the product liquor with sodium chloride. The sodium chloride and triple salt ($NaOH-NaCl-Na_2SO_4$) precipitated in the liquor flash tank and cooling system is removed from the cooled product liquor with centrifuges. The salt precipitated in the three effects flows countercurrent to the liquor flow so that all of the salt is discharged from the last effect, the effect that has the coldest liquor and the lowest caustic soda concentration.

Two-stage steam-jet air ejectors with a common intercondenser are used to maintain vacuum in the evaporator. In the caustic cooling system, agitated tanks are used to cool the slurry discharged from the liquor flash tank. The slurry flows from the cooling system to the centrifuge feed tank from where it is pumped into centrifuges. Salt discharged from the centrifuges drops into the evaporator feed tank, where it is dissolved in cell liquor. The 50 wt % NaOH concentrate liquor, which flows by gravity to the pressure filter feed tank, contains ca. 1.0–1.5 wt % dissolved NaCl and ca. 0.1 wt % crystalline NaCl.

The liquor is pumped from the pressure filter feed tank into the pressure leaf filters, where the remaining traces of salt crystals are removed. The product caustic flows by gravity to the filtered product tank and then is pumped to storage. Salt removed in the pressure filters is reslurried with cell liquor and pumped to the evaporator feed tank via the filter backwash pump.

The salt discharged from the centrifuges drops into the leaching tank, where it is reslurried with condensate and recycled brine from the Glauber's salt ($Na_2SO_4 \cdot 10\,H_2O$) crystallizer. Concentrate from the pusher centrifuges flows by gravity into the evaporator feed tank.

The product salt is discharged from a cyclone into the salt reslurry tank. The overflow from the cyclone is returned to the leaching tank. The product salt is diluted with brine and pumped to the resaturator tank.

Brine containing the dissolved sodium sulfate is separated from the salt crystals in a cyclone. The underflow returns to the leaching tank. The overflow is collected in the feed tank for the Glauber's salt crystallizer. Sodium sulfate is crystallized from the liquor in a continuous vacuum cooled crystallizer.

Mother liquor removed from the crystallizer is pumped under level control to the brine tank. Slurry discharged from the crystallizer is thickened to ca. 50 wt %. The liquor from the thick-

ener is collected in the brine tank and pumped back to the leaching tank. The thickened slurry is redissolved in the Glauber's salt dissolving tank and pumped to a waste treatment system.

Caustic Purification [127]. Diaphragm-cell chlor-alkali producers requiring higher purity caustic than that produced by the diaphragm process can use caustic purification or DH process (Fig. 42). *Salt removal* in the purification unit is effected by contacting the 50 wt % caustic with anhydrous liquid ammonia under pressure sufficiently high to maintain all materials in the liquid state.

The liquid ammonia absorbs salt, chlorate, carbonate, water, and some caustic. It is then stripped, concentrated, and returned to the extraction process. The concentrated caustic leaving the extractor is stripped free of ammonia, which is recovered, concentrated, and recirculated. Typical purities before and after caustic purification are shown in Table 20. This process is offered for license by PPG Industries and OxyTech Systems.

In addition, producers and users of diaphragm-cell caustic may wish to *reduce metal impurities* by utilizing the porous cathode cell process (PPG Industries) [128]. The process consists of an electrolysis cell with porous nonmetallic cathodes. The caustic soda (50 wt %) is freed from iron, nickel, lead, and copper, which are deposited on the cathode. The cell must be regenerated periodically with water and hydrochloric acid. Typical feed and product analyses based on anhydrous NaOH are

Metal	Content, ppm	
	Feed	Product
Iron	10.0	2.0
Nickel	3.0	0.2
Lead	4.0	0.4
Copper	0.2	0.1

6.3.5. Measurement

Recorded data is an important tool for determining the operating condition of the plant and diagnosing problems.

The following should be recorded continuously or hourly:

ampere load on each circuit
voltage for each circuit
chlorine header pressure
hydrogen header pressure
brine header pressure or flow rate
brine temperature
brine pH
cell liquor temperature

Samples of brine should be taken every 4 h and combined into a daily composite. In addition, samples of cell liquor should be taken from each cell string, the sodium hydroxide content analyzed, and the temperature taken every 4 h. A daily composite should be made and samples should be analyzed by the laboratory for the following:

NaOH content
NaCl content
salt : caustic ratio
$NaClO_3$ content
NaOCl content
Fe content
average temperature
specific gravity at 25 °C

Chlorine gas from each cell circuit should be analyzed for chlorine and hydrogen content at least twice each 8-h shift. Each day a complete analysis of the chlorine header gas should be made. Additions or extensions to list may be dictated by plant operation.

Each plant must develop a procedure for taking *individual cell data* so that individual cells may be scheduled for renewal. The following is a minimum schedule:

weekly	voltage and cell liquor composition (NaOH, NaCl, $NaClO_3$)
monthly	chlorine composition (Cl_2, O_2, H_2, CO_2, N_2)

7. Membrane Process

In the membrane process, the anolyte and catholyte are separated by a cation-exchange membrane that selectively transmits sodium ions but supresses the migration of hydroxyl ions from the catholyte into the anolyte. A strong caustic soda solution with a very low sodium

chloride content can be obtained as the catholyte efflux. The advantages of the membrane process are its energy efficiency and its ability to produce caustic soda of high quality, with almost no impact on the environment. Depending on the particular design, membrane sizes from 0.2 to 5 m^2. The production capacity of an electrolyzer can be up to 90 t/d NaOH (100 %).

The process was started in the early 1970s with development of the perfluorosulfonate membrane Nafion by DuPont [129]. In 1975, a perfluorocarboxylate membrane capable of producing 35 wt % caustic soda became available, from Asahi Glass in Japan [130]. In 1978 the first two-layer membrane was developed, with low electrical resistance and high current efficiency [131].

The industrial success of the membrane process started in Japan, where the abolition of the mercury process on environmental grounds had been promoted by the government. Today the membrane process is the state of the art process for producing chlorine and caustic soda or potassium hydroxide.

The production capacity of chlor-alkali plants using the membrane process reached about 21 % of total world production capacity in 1995 and is predicted to increase to about 28 % in 2001 [132].

7.1. Principles

In a membrane cell a cation-exchange membrane separates the anolyte and catholyte, as shown in Figure 43. Saturated brine is fed into the anode compartment, where chlorine gas is evolved at the anode:

$$2\,Cl^- \rightarrow Cl_2 + 2\,e^-$$

Figure 43. Principle of the membrane cell

The anolyte is discharged from the cell. The electric field causes hydrated sodium ions to migrate through the membrane into the catholyte. In the cathode compartment, hydrogen is evolved at the cathode, leaving hydroxyl ions, which together with permeating sodium ions constitute the caustic soda:

$$2\,H_2O + 2\,e^- \rightarrow H_2 + 2\,OH^-$$

$$Na^+ + OH^- \rightleftarrows NaOH$$

Liquid and gaseous phases anolyte/Cl_2 and catholyte/H_2 can be separated either in the cell compartment or downstream of the cell outlet. The chlorine-saturated anolyte is then treated in a dechlorination unit to recover the dissolved chlorine.

Membrane.

Structure. The membrane is exposed to chlorine and anolyte on one side and strong caustic solution on the other side at high temperature (90 °C). Only ion-exchange membranes made of perfluoropolymer can withstand such severe conditions. The ion-exchange groups of the original polymers are in the fluorosulfonate form, $-SO_3F$, or the carboxylate form, –COOR.

$m = 0 - 1$

Fluorosulfonate form

Carboxylate form $m = 0 - 1$ $n = 1 - 5$ $R =$ alkyl

The first membranes that showed significant potential for use in the chlor-alkali process were made of a perfluorosulfonate layer. These proved to be durable in chlor-alkali cells but were relatively inefficient. The perfluorocarboxylate polymers, with a lower water content,

showed higher selectivity but led to higher electrical resistance and high electrical power consumption [133]. Combining the advantages of high current efficiency and low electrical resistance a composite membrane (Fig. 44) was developed with a layer containing SO_3^- groups on the anode side and a layer containing COO^- groups on the cathode side [131, 134]. The perfluorosulfonate layer is thicker than the perfluorocarboxylate one and is the major constituent of the membrane [133].

Figure 44. Membrane structure

Flux through the Membrane. The total flux through the membrane can be divided in to three parts [133]:

1) Migration due to electric field
2) Convection
3) Diffusion due to chemical gradients

Migration is the flux of ions through the membrane, driven by electric field. This includes the desired transfer of sodium ions to the cathode compartment and the undesired transfer of hydroxyl ions to the anode compartment. The capacity for selective separation of the cation exchange membrane is determined by its repulsive force for hydroxyl ions. This effect determines the current efficiency.

The backmigration of hydroxyl ions increases the formation of oxygen, hypochlorite, and chlorate in the anode compartment and causes a loss of current efficiency of 3 – 7 % in caustic soda production. The evolution of oxygen gas can be depressed by selecting an anode coating with suitable characteristics (see Section 8.1) or by decreasing the pH in the anode compartment by acidifying the inlet brine (Fig. 45).

Figure 45. Oxygen content in chlorine [135]

Convection and diffusion determine the flow of uncharged compounds and ions through the membrane. Chloride anions in the catholyte are excluded by the cation-exchange membrane and repelled by the electric field, so that the transfer rate of chloride anions from the anolyte is extremly low. As a result, a caustic soda solution of about 32 – 35 wt % with a salt content of less than 20 ppm can be obtained. The water transport through the membrane is about 3.5 to 4.5 moles of water per mole of sodium ions, and can be regarded as the hydration sphere of the migrating sodium ions. Water flux increases with decreasing anolyte concentration [136].

Migration, convection and diffusion influence each other, and the resulting flux depends on membrane type, current density, temperature, and composition of anolyte and catholyte.

Cell Voltage. The cell voltage of a membrane cell is composed of the following terms:

1) Decomposition voltage
2) Membrane potential between anolyte and catholyte
3) Electrode overpotentials for chlorine and hydrogen
4) Ohmic drop in the membrane
5) Ohmic drop in the electrolytes
6) Ohmic drop in electrodes and conductors

Term 1. The decomposition voltage of the chlor-alkali process is about 2.20 V, depending on temperature, concentration, and pressure.

Term 2. This term describes the overpotentials at the surfaces of the membrane. Under standardized operating conditions (3 kA/m^2, 90 °C, 32 wt % caustic solution), the membrane potential is approximately 0.08 V.

Term 3. Titanium anodes coated with oxides of Ir, Ru or Pt are generally used in membrane cells and lead to a chlorine overvoltage of approximately 0.05 V at 3 kA/m^2. Hydrogen overpotentials of about 0.1 V at 3.0 kA/m^2 are attained with activated cathodes. Mainly nickel substrates are coated by painting and thermal treatment or galvanic deposition [137, 138]. Coating materials include Ni, Co, Ru and others (see Section 8.2).

Term 4. The ohmic drop of advanced commercial membranes under standardized operating conditions is about 0.25 – 0.30 V at 3 kA/m^2.

Term 5. To minimize the ohmic drop of an electrolyte, the gaps between the membrane and the electrodes are minimized in membrane cells. However, if the gap is very small, a rise in voltage is observed due to the entrapment of gas bubbles between the electrodes and the hydrophobic fluoropolymer membrane.

Term 6. The voltage losses in the electrolysis cell that occur due to unfavorable current paths along the metallic structure are reduced by an appropriate design. In modern chlor-alkali electrolysis cells the typical ohmic drop is 20 – 40 mV at 3 kA/m^2.

Current Efficiency. The current efficiency (CE) for caustic soda can be obtained either by directly measuring the quantity of caustic soda produced or by an anodic balance, i.e., the compositions of the anode gas and the anolyte with the following equation:

$$\mathrm{CE}\,(\%,\mathrm{NaOH}) = 100 - \eta\mathrm{O_2} - \eta\mathrm{ClO_3} - \eta\mathrm{ClO} + \eta\mathrm{NaOH} + \eta\mathrm{Na_2CO_3}$$

where ηO_2, ηClO, and ηClO_3 represent the loss of current efficiency due to the generation of oxygen hypochlorite, and chlorate, while $\eta NaOH$ and ηNa_2CO_3 take into account NaOH and Na_2CO_3 introduced in the feed brine.

The current efficiency is mainly dependent on membrane performance. On the cathode side the membrane is in contact with a concentrated NaOH solution, while the anode side has a pH of approximately 2 – 4. This leads to a pH gradient across the membrane cross section. The solubility of impurities, which are always present in the pure brine, depends on the pH. Therefore, depending on the type of impurities and on the pH, precipitation inside the membrane can take place. This leads to mechanical destruction of the membrane, which has a irreversible effect on current efficiency. In addition, the cell voltage rises due to the crystals formed inside the membrane.

7.2. Process Specific Aspects

The performance of a membrane cell depends on the following operating conditions:

1) Concentration of anolyte and catholyte
2) Current density
3) Temperature
4) Brine impurities

The optimum caustic strength depends on the composition of the membrane polymer. To achieve stable operation with high current efficiency, fluctuations in operating conditions or upsets must be avoided. Fluctuations in the caustic strength beyond the optimum range influence both the current efficiency and the cell voltage, as shown in Figure 46 [131]. Dilution of the anolyte caused by an upset in the brine feed also decreases the current efficiency. The sensitivity of membrane performance to operating conditions is attributed to changes in the water content of the membrane.

Figure 46. Dependence of cell voltage and current efficiency on NaOH concentration [139]

7.2.1. Brine Purification

The introduction of membrane technology into chlor-alkali electrolysis has dramatically increased the demands on brine purity [140]. The lifetime of chlor-alkali membrane cells is determined by the operating conditions and the quality and purity of the feed into the electrolyzers. Good long-term performance of the cells may be obtained if brine impurities are kept within the limits recommended in Table 14.

A major source of performance decline is the accumulation of solid material in the membrane [141]. Specific impurity levels are dependent on membrane design, cell design, operating conditions, the impurity itself and other impurities present. The prerequisite for long membrane life is to maintain low levels of, for example, Ca^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}, Al^{3+}, SO_4^{2-} and SiO_2 in the brine. Traces of these impurities damage the membrane and/or electrodes and result in irrecoverable decreases in current efficiency and/or increased cell voltage. In the case of a closed brine loop with no purge, each impurity brought into or formed in the system must be removed to keep it below its specification level and to prevent accumulation.

The contaminants can be brought into the brine system by salt, by chemicals used in brine purification steps, by water for dissolving the salt, from materials of tanks, pipework, and cell components, or by the process itself [141]. The impurities in the salt depend upon the origin of the raw material. Rock salt, vacuum salt, sea salt, brine from well mining, or salt from waste incinerators serve as supplies of NaCl. The more varied the sources are, the more diverse the impurities.

Membrane and electrode damage effect cell performance, i.e., cause lower current efficiency, increased cell voltage, and, as a result, increased power consumption [142]. Some impurities affect the anode or cathode coating and cause an increase in overvoltage or simply deposit in the membrane, increasing its resistance and thus the cell voltage. The increase in voltage may in some cases be partially reversible when the impurity concentration drops to the recommended limits.

Current efficiency declines are strictly related to the membrane. Impurities lower the current efficiency by reducing the membrane's ability to reject anions, specifically the ability to prevent hydroxyl ions from migrating from the cathode compartment through the membrane to the anode compartment [143]. This is usually a result of physical damage caused by precipitation and crystallization of impurities inside the membrane. Impurities precipitate because the environment in the membrane changes from an acidic salt solution (pH 2 – 4) to a caustic solution (pH 14 – 15) over the 100 – 300 μm thickness of the membrane.

It is important to consider not only the impurities themselves but also their interaction. The presence of one impurity may not be harmful, but its synergistic combination with others may be [143]. For example, silica itself is not harmful for membranes. Only in the presence of calcium and aluminum do precipitates form and damage the membrane irreversibly. The concentration of silica and/or the concentration of aluminum plus calcium can be adjusted to give the optimum operating conditions. For example, with an effective secondary brine purification, higher levels of silica can be tolerated. Similarly, if aluminum concentration is high, calcium or silica concentration must be reduced to maintain acceptable membrane performance.

To meet the strict requirements on brine purity outlined in Table 14 brine treatment is generally carried out in the following main steps in the brine loop: saturation, precipitation, clarification, filtration, polishing filtration, ion exchange, electrolysis, chlorate decomposition and dechlorination.

Calcium and magnesium are precipitated and separated from the saturated brine with the insoluble materials. A ca. 10 wt % sodium carbonate and barium carbonate (barium chloride) solution and 32 wt % caustic soda are used as precipitants.

$$Ca^{2+} + Na_2CO_3 \rightarrow CaCO_3 + 2\,Na^+$$

$$SO_4^{2-} + BaCO_3 \rightarrow BaSO_4 + CO_3^{2-}$$

$$Mg^{2+} + 2\,NaOH \rightarrow Mg(OH)_2 + 2\,Na^+$$

Alternatively:

$$SO_4^{2-} + BaCl_2 \rightarrow BaSO_4 + 2\,Cl^-$$

From the precipitation tank, the brine is fed into the clarifier, where a defined quantity of flocculant is added to promote the settling of the precipitated solids and gels. The brine is then pumped to a filtration system followed by an ion exchange purification.

Additionally, if the brine circulating system of an existing mercury cell plant also serves membrane cells, all mercury must be removed in a chemical treatment facility. The brine from the primary filtration is acidified with hydrochloric acid to pH 2.0 – 2.5 and sodium sulfide is added to precipitate mercury sulfide. Subsequently, the brine is filtered, alkalized to pH 9.5 – 11 by adding caustic soda, and finally fed to the secondary purification section.

The content of calcium and magnesium must not exceed 20 ppb. Such low contents can be achieved by using ion-exchange columns. The polished brine is pumped at approximately 70 °C to an ion-exchange system with two resins beds operating in series according to the lead/lag principle. When the leading ion exchanger is exhausted it is put to the regeneration and conditioning mode, while the lagging one takes over the lead position. After treatment in this secondary purification step, the purity limits are met and the brine is fed to the membrane cells. In another secondary purification system two columns operate in series while the third is in regeneration mode. When the first column is exhausted, the regenerated column is put in second position.

Prior to the resaturation, the byproduct chlorate and dissolved chlorine must be eliminated from the anolyte. Chlorate concentration is controlled by acidification of a partial stream of anolyte with an excess of hydrochloric acid [143]. Chlorine is removed under vacuum followed by addition of sodium bisulfite and hydroxide.

$$NaClO_3 + 6\,HCl \rightarrow NaCl + 3\,Cl_2 + 3\,H_2O$$

$$2\,Cl_2 + 2\,NaHSO_3 + 6NaOH \rightarrow 4NaCl + 4\,H_2O + 2\,Na_2SO_4$$

All other impurities not precipitated, filtered out, or extracted by the ion exchangers can only be controlled by purging a partial stream of the anolyte to avoid accumulation. Resaturation then closes the loop.

7.2.2. Commercial Membranes

The ion-exchange membrane is the key component of the membrane cell. The energy consumption and the quality of the products depend on membrane performance. Requirements for the membrane are as follows:

1) Durability under the conditions of chlor-alkali electrolysis
2) High selectivity for sodium ion transport
3) Low electrical resistance
4) Sufficient mechanical strength for practical use
5) Low sensitivity to changing operating conditions

The importance of 1 – 3 is described in Section 7.1. High mechanical strength is necessary for installing the membrane and during service life, in which the membrane has to cope with deviations in temperature, concentration, and pressure.

As the performance of the membrane is the most important element in the economy of a membrane cell, many refinements have been made in membrane manufacturing. To reduce the current screening due to fabrics, membranes reinforced with dispersed microfibers and interwoven fabrics made of electrolyte-soluble fibers and PTFE have been developed [144, 145].

The improvement of hydrophilicity by covering the surface on the cathode side or on both sides with a nonconductive inorganic material brought about a significant reduction in the cell voltage. The surfaces of the membrane are covered with thin layers of a porous inorganic material. This material is an oxide, hydroxide, or carbide of the metals of groups 4, 5 and 6 or the iron triad (Fe, Co, Ni) [138, 146].

Figure 47 illustrates the effect of hydrophilic cathode surface modification. The surface-modified membrane (Type B) has a lower cell voltage than the conventional membrane (Type A). Tthe voltage of the surface-modified membrane decreases linearly with decreasing gap size. With these advanced membranes, so-called zero-gap cells have been made possible, and the ohmic loss in electrolytes has been reduced to a minimum.

The active life of a membrane is determined by the economic balance between membrane cost and energy cost in use [148].

Figure 47. Effect of cathodic surface modification

The performance of membranes depends on the operating conditions, especially on the caustic strength of the solution (Figure 46). Commercially available membranes, delivered by Asahi Chemical, Asahi Glass and Du Pont, are designated for use in a specific strength of caustic. For economic production the selection of the appropriate membrane is essential. Table 15 gives an overview of the most widely used membranes. Most membranes are operated in the narrow- or zero-gap configuration to minimize power consumption.

7.2.3. Power Consumption

For monitoring cell performance and comparing different electrolyzer designs, the electric power required to produce one tonne of NaOH 100 % is considered. This figure is determined by the voltage drop over one cell and the NaOH current efficiency.

$$\frac{\text{DC Energy}}{100\%\ \text{NaOH produced}} = \frac{UIt}{M} = \frac{U}{F \cdot \text{CE}} = \left[\frac{\text{kWh}}{\text{t}}\right]$$

where U is the cell voltage (V), F the Faraday constant for NaOH (1.4923 kg/kAh), and CE the NaOH current efficiency (%).

The specific power consumption is the main indicator for economic plant operation, and continuous efforts are made to lower the voltage and increase the current efficiency. At a thermodynamic minimum the decomposition voltage of about 2.2 V limits the theoretical minimum energy requirement to about 1480 kWh/t 100 % NaOH, as shown in Figure 48. At practical current densities of 3.0 – 5.5 kA/m^2 for present-day commercial cells and membranes, power consumption measured at the electrolyzer terminals is in the range of 1950 to 2180 kWh/t 100 % NaOH dependent on the selected current density (anolyte/catholyte temperature 90 °C, NaOH concentration 32 wt %, NaCl concentration in the anolyte 220 g/L). The power consumption rises with increasing operating time due to aging effects, such as decreasing current efficiency and increasing voltage. Investment costs rise when operating at low current densities, as more cells are needed to meet production. Hence electrolyzers are operated at low current densities in countries with high energy prices, and at high current densities in countries with low energy prices.

7.2.4. Product Quality

The caustic soda solution has a concentration of up to 32 ± 1 wt % NaOH. If a NaOH concentration of 50 wt % is required, evaporation can be used. The typical NaCl content is 20 ppm in a 32 wt % caustic solution.

The hydrogen has almost synthesis quality with a concentration of about 99.9 vol % H_2 (dry basis). The chlorine has an oxygen content of about 1.5 vol % (dry basis). Chlorine with an oxygen content below 0.6 vol % (dry basis) can be obtained by acidifying the brine with hydrochloric acid.

7.3. Membrane Cells

7.3.1. Monopolar and Bipolar Designs

A commercial membrane plant has multiple cell elements combined into a single unit, called the

Figure 48. Specific power consumption

electrolyzer. The electrolyzers follow two basic designs: monopolar and bipolar [147].

In a bipolar arrangement the elements are connected in series with resultant low current and high voltage. The cathode of a cell is connected directly to the anode of the adjacent cell, as shown in Figure 49. The operation of a bipolar electrolyzer can be easily monitored by measurement of element voltages. If element upsets occur, a safety interlock system actuates the breakers (short-circuiting switches) and isolates the electrolyzer from the electric circuit. As the influx and efflux of electrolytes for the cells with different electric potential are gathered in common headers, problems of stray current may arise.

In the monopolar type all anodes and cathodes are connected in parallel, forming an electrolyzer with high current and low voltage (Figure 50). Due to the long current path, the voltage drop is high and can only be reduced by minimizing the size of cells or introducing internal copper conductors to lower the resistance. Because of this basic principle, ohmic losses in the monopolar cells are 80 – 100 kWh per tonne 100 % NaOH, which is much higher than in equivalent bipolar cells. Furthermore, the bipolar safety system is not applicable to the monopolar design, since the cell elements are arranged in parallel, which does not permit the monitoring of deviations in individual cell voltages.

Figure 49. Bipolar electrolyzer

Figure 50. Monopolar electrolyzer

Multiple electrolyzers are employed in a single d.c. circuit (Fig. 51). Usually bipolar electrolyzers are connected in parallel with low current and high voltage. Monopolar electrolyzers are often connected in series, resulting in a high current circuit and low voltage. Though both principles still appear on the market, investment and operating cost considerations, such as for the rectifier system, the cell room space required, for piping, valves, instrumentation, busbars and switches, significantly favor the bipolar design.

Figure 51. Electrolyzer architecture

7.3.2. Commercial Electrolyzers

Generally, membranes are clamped vertically between the meshlike metal anodes and cathodes. The effective membrane area of a cell ranges from 0.2 to 5.0 m^2. Current density varies between 1.5 and 7 kA/m^2.

The cells are filled with electrolytes, and gas-separating means are provided outside the cells. Many cells generally stacked like a filter press, constitute one electrolyzer with high production capacity.

The performance of a plant is determined by the electrolyzer, the cell voltages, and the current efficiency of the membrane. It is essential to design an electrolyzer with an homogeneous electrolyte concentration, temperature, and current density distribution across the whole area of the membrane.

The construction materials of the cell are selected to withstand the corrosive electrolytes. In most electrolyzers, titanium and nickel are used for the anode and cathode compartments of the cell. In older electrolyzers, stainless steel is used on the cathode side.

For economic and environmental reasons, mercury and diaphragm plants are increasingly being converted to membrane electrolyzers. The existing facilities, such as rectifiers, equipment for brine purification, and equipment for product treatment are utilized as much as possible.

Asahi Kasei ACILYZER-ML/NC Electrolyzer. The Asahi bipolar electrolyzer (Fig. 52) is of the filter-press type. The bipolar cell frames are suspended in a steel frame and compressed by a hydraulic device. Each cell frame consists of an anode and cathode compartment separated by a partition wall. The anode compartment is made of titanium, and the cathode compartment consists of special stainless steel and nickel. The anode and cathode structures are spot welded onto ribs in each compartment. Each compartment has an inlet nozzle for electrolytes at the bottom and an outlet nozzle for gas and electrolyte on top, connected to the gas/liquid separation chamber.

Two types of cell frames are available: frames with forced circulation of electrolytes by pumps, and frames with natural circulation in each compartment by means of a special arrangement of integrated ducts. The current is connected to the first and last element by flexible busbars.

CEC BITAC 800 Electrolyzer. The Chemical Engineers Corporation (CEC) bipolar BITAC electrolyzer was jointly developed with

Tosoh Corporation. The design follows the filter-press principle. Up to 80 bipolar electrode frames are clamped together by end plates and spring-loaded tie rods. The frames are made of special titanium alloy for the anode and nickel for the cathode. The electric current flows along the nickel pans, since the electrical conductivity of nickel is six times higher than that of titanium. Gas and electrolytes leave the cell compartment in overflow mode with little pressure fluctuation. Transparent PTFE tubes are attached at the electrolyte inlet and outlet nozzles of each element. Anolyte recirculation takes place through an external loop.

CEC CME DCM 400 Electrolyzer. The CME monopolar electrolyzer consists of large elements compressed in a filter-press arrangement. The electric current travels into each anode element through conductor rods and current distributors. This design achieves uniform current distribution over the large electrode area. The current distributors serve the additional role of a downcomer pipe, which creates a natural circulation within the cell, providing a uniformly distributed electrolyte concentration as well as good gas release. The anode frames are constructed from titanium and the cathode frames from a special stainless steel. The rods are cladded with titanium and stainless steel. Inlet and outlet tubes for liquids and gases and are made of transparent PTFE.

Uhde BM 2.7 Electrolyzer. The bipolar Uhde electrolyzer (Fig. 53) is a single-element concept. Each element comprises anode and cathode half-shells, electrodes, a membrane, flanges, and the sealing system. This enables long-term storage of pre-assembled and fully tested elements. The electrodes are attached with continuous laser weld to the current transfer and support blades and hence to the half-shells. The anode is made of titanium and the cathode of nickel. The individual cell elements of an electrolyzer are suspended in a steel frame in which they are lightly pressed together for electrical contact. Large sealing forces are not required in the single-element concept, as each element is a separate, stand-alone electrolysis cell. The feed and discharge lines of the cell are located underneath the cells and connected to the catholyte and anolyte headers. The area above the electrolyzer is free of piping or bus bars, simplifying access and eliminating the risk of leakage and associated corrosion problems. The current is conducted from cell to cell by continuously laser-welded, explosion-bonded titanium – nickel contact strips on the anode half-shell.

Figure 53. Uhde BM 2.7 electrolyzer
a) Single element; b) Contact strip; c) Cell rack; d) Busbars; e) Inlet hoses; f) Outlet hoses; g) Header

The brine and caustic soda feeds enter the cell at the bottom, and the product streams are discharged downwards through internal overflow pipes. The internal baffle plate at the top of the anode half-shell prevents gas-phase blistering of the membrane. The chlorine gas is effectively removed from the membrane, preventing contact and improving the inherent safety of the electrolyzer. Natural circulation around a downcomer plate and a distribution pipe for brine and caustic achieve homogeneous temperature and concentration profiles within the element and assist in achieving uniform current distribution.

EL-Tech ExL^{B} Bipolar Electrolyzer. The ExL^{B} bipolar electrolyzer (Fig. 54) is basically of the same design as the EL-Tech ExL^{M} electrolyzer. Instead of the copper distributors with interface material, which provide the parallel (monopolar) arrangement in the electric circuit, the elements are connected in series (bipolar), omitting the copper distributors and simply pressing the nickel cathode pan onto the nickel-plated back of the anode pan. The integral feed and discharge manifolds are designed to avoid current leakage.

EL-Tech ExL^{M} Monopolar Electrolyzer. The ExL^{M} monopolar electrolyzer is an improved version of the MGC electrolyzer, which has been in service for more than 15 years. The elements are sealed with O-rings in a staggered gasket design. The cathode O-ring is located closer to the liquid than the anode O-ring. This protects the anode O-ring from the chlorination degradation, making it a long-life back up seal. The elements are pressed together by tie rods with copper distributor plates and conductive interface material to provide good current distribution. Electrolytes and gases are fed and discharged to and from the elements through the manifold passage attached to the cell ele-

Figure 54. EL-Tech ExL^{B} bipolar electrolyzer

ments. Increased internal electrolyte circulation is achieved by an improved electrode design.

EL-Tech ExL^{DP} Dense Pak Unit Electrolyzer. The EL-Tech ExL^{DP} dense pak electrolyzer comprises monopolar sections in one electrolyzer filter press compression set using standard monopolar cell components. Each monopolar cell section is separated by an insulating Inter Pak Spacer. Mostly three monopolar electrolyzer sections are included, with 2 to 10 elements per section. The dense pak can be configurated to match special rectifier/transformer configurations of existing plants, making it suitable for mercury and diaphragm cell conversion projects. For new plants, the advantage of the ExL^{DP} electrolyzer is reduced current, increased voltage circuits compared to an equivalent monopolar cell unit.

INEUS FM21-SP Electrolyzer. The FM21-SP (Fig. 55) is a monopolar electrolyzer incorporating a simple pressed electrode structure. The anode assembly is composed of a 2 mm thick titanium panel between compression molded joints of a special cross-linked EPDM elastomer. The cathode assembly is composed of a 2 mm thick nickel panel between compression molded joints, also of EPDM.

The anodes and cathodes are assembled between 2 end plates until the number of electrodes required for the desired electrolyzer capacity is reached, up to 60 anodes in the FM21-SP and up to 90 anodes in the larger FM1500. A key feature of both designs is the elimination of any external piping to individual cell compartments by the use of a simple but effective internal header/manifold arrangement.

Figure 55. INEUS FM21-SP elelctrolyzer
a) Tie-rod; b) Floating end plate; c) Copper electrical connections; d) Ion exchange membrane; e) Fixed end plate; f) Anode electrode assembly (titanium panel between compression molded gaskets; g) Cathode electrode assembly (nickel panel between compression molded gaskets); h) Support rail

The electrolyzer has coated titanium anodes. The cathodes are pure nickel, also available with a coating to lower the hydrogen overpotential if necessary. Both electrodes are pressed from integral sheets of pure metal, and this makes recoating of the electrodes extremly simple and cost effective. Hence recoated structures can be sent to site prior to electrolyzer refurbishment from a pool of electrodes available to all customers.

Effective electrode area is $2 \times 0.21\,\mathrm{m}^2$ per electrode, which gives a very compact electrolyzer. The individual electrodes are readily handled without the need for lifting apparatus, which allows the electrolyzer to be rebuilt and refurbished in the minimum of time.

7.3.3. Comparison of Electrolyzers

Operating parameters of bipolar electrolyzers are compared in Table 16, and those of monopolar electrolyzers, in Table 17.

7.3.4. Cell Room

Typical bipolar membrane cell rooms are shown in the following Figures 56 and 57.

The media are fed to and discharged from the electrolyzers by a header system arranged along the walls of the cell room on one side.

From the other side power is supplied either from separate transformer/rectifier units for each electrolyzer or from one unit for two or more (up to six) electrolyzers in parallel. The switches are arranged close to the rectifiers. They are actuated automatically and connected to the common interlock system for safety reasons.

In the middle space remains available for the electrolyzers and their individual feed and discharge piping. Only a light crane is required to handle single electrode frames or elements. Thus only a light structure for the entire cell house is used.

8. Electrodes

8.1. Anodes

The initial anodes used for the electrolytic generation of chlorine were made of platinum or magnetite. However, as the plant grew in the size, the cost of platinum and limitations of the current density for magnetite led to the wide-scale introduction of graphite anodes, which were used exclusively up to 1970. The graphite of choice was

low in ash and vanadium and composed of various types of particulate coke and pitch binder. Following extrusion, baking at ca. 1000 °C, and graphitization at 2600 – 2800 °C, the final shape of the electrode was achieved by machining. The shape of the horizontally suspended anodes with an initial thickness of 7 – 12 cm for the amalgam process was similar to that of modern titanium anodes due to the retrofitting of existing cells. The anodes had vertical slits and holes to allow the removal of the gaseous chlorine. Due to the cogeneration of oxygen and the resulting formation of CO and CO_2, electrode wear was high, in the range of 1.8 – 2.0 kg graphite per tonne of chlorine from NaCl and 3 – 4 kg per tonne from KCl. Even with a daily adjustment of the anodes to compensate for the changes in dimension a k value of only 0.12 to 0.14 $Vm^2\ kA^{-1}$ was achievable.

The initial attemps to replace the graphite anodes with activated titanium anodes began as early as 1957 with platinized titanium and Pt/lr-coated anodes. However because of the short lifetimes of the anodes, they were not economic. The use of mixed metal oxides was first patented by Beer in 1965 and 1967 [149]. The initial patent described a coated metal electrode in which the active material was a mixed metal oxide coating containing one or more of the platinum metal group oxides. The second patent described coatings in which mixed metal oxide crystals contained a non-platinum metal oxide in addition to the platinum metal oxide (including Ti, Ta, and Zr oxides).

Further improvements in the coating and the anode structures followed rapidly along with the commercialization of anodes by De Nora [150] under the trade name Dimensionally Stable Anode (DSA). Because of the dimensional stability and the lifetime of the coating and the ability to increase the current densities, rapid introduction of the activated titanium anodes was possible. At present only a few plants still use graphite anodes, largely due to the initial investment costs for titanium anodes.

8.1.1. General Properties of the Anodes

Coating Properties and Preparation. Comprehensive reviews on preparation and properties are given in [151, 152].

Chemical Composition. Because of its price and performance, Ru is the basic component in all commercial coatings at present,

along with an oxide of a non-platinum metal (e.g., Ti, Sn, or Zr). In most cases a second platinum metal oxide is added to increase the performance of the anode coating. There is an optimum ratio of platinum metal oxides to non-platinum metal oxides in terms of overpotential, wear rate, and costs. The optimum depends on the operating conditions and the method of preparation of the coating and normally lies in the range of 20 : 80 to 55 : 45 by weight. Some of these coatings may contain glassy fibers [153] and some contain pre-oxidized material such as $Li_{0.5}Pt_3O_4$ [154].

Preparation. The solvent used for the preparation of the precursors solutions are chosen on the basis of the desired electrochemical properties and the method of application, which is mainly determined by the anode structure. Most coating solutions are prepared by dissolving salts or organometallic complexes in aqueous, organic, or mixed solvents. The coating can be applied by spraying, brushing, dipping, or other techniques. Following evaporation of the bulk of the solvent, the anode is heated to 350 – 600 °C to form the oxidic coating then cooled prior to the next coating cycle. This is repeated until the desired coating thickness is applied. Optional post-thermal treatment can also be carried out.

The optimal performance of the coating depends on the above parameters and on the coating thickness per coating cycle, which must be optimized for each coating and surface pretreatment step.

Crystallographic Composition, Morphology, and Real Surface Area. A rutile phase is the electrochemically active phase of the coating, and although it is thermodynamically unstable, it remains even after many years of operation. The stable phase – anatase TiO_2 in the case of $TiO_2 - RuO_2$ coatings – is electrochemically inactive [155]. The degree of crystallinity and the composition are related to the processing parameters [156] and the various degrees of mixed crystals exhibit different stabilities. The real surface area of the coating is a function of both the titanium pretreatment and the coating composition. The surface of the chlorine-generating coating is often described as "cracked mud" due to its resemblance to a dry river bed. The BET surface area of the coatings or that determined electrochemically vary ca. 400 to 1000 times the geometric surface area [157].

Overpotential and Current – Voltage Relationship. The observed overpotential for chlorine evolution at 2 – 10 kA/m^2 is in the range of 80 – 110 mV [158 – 161], about 70 – 100 mV of which is due to diffusion overpotential effects [161]. The overpotential for the generation of oxygen under similar pH and temperature conditions lies is ca. 300 mV more anodic than that of chlorine generation. Other than oxygen evolution, the only other side reaction is formation of chlorate.

Coating Wear and Coating Lifetime. The coating lifetime is strongly dependent not only on the type of cell – membrane, diaphragm, or mercury – but also on a range of process parameters, including brine quality, current density, and membrane or diaphragm quality. The upper limit of the wear rate would seem to be in the region of 500 t Cl_2/m^2 anodic area for a standard commercial loading.

The wear rate mechanism is discussed in detail in [162, 163]. The effects of various impurities and materials in the brine can be divided into three types.

1) Compounds or ions which attack the substrate, e.g., fluoride or organic acids such as formic or oxalic acid.
2) Materials which built up blocking layers on the surface of the anode, e.g., hydraulic oil or polymer films resulting from delamination of membranes. The irreversible poisoning of coating is caused by ultrathin aluminum silicate layers.
3) Electrochemically active film-forming materials such as MnO_2, which may lead to an increased oxygen content in the chlorine.

Other examples, such as the insensitivity of the performance of diaphragm anodes to almost complete surface coverage by iron oxides illustrate the robustness of commercial coatings.

8.1.2. Anodes for Mercury Cells

Structure. The classical structure of anodes for this process still reflects the retrofitting concept used during the 1970s and the high current

operations at ca. 10 kA/m^2. A typical mercury cell anode consists of a number of copper shafts, protected by either a permanently welded or removable titanium outer sleave, from which the current is distributed to the active surface over distributor bars (Fig. 58).

Figure 58. Four-stem anode for amalgam cells
a) Active surface; b) Current distributor; c) Riser tube to protect the copper bar inside

The quick release of gas and the supply of fresh brine to the active surface are the major requirements of an mercury cell anode, and a wide range of designs have been built. The most common types are shown in Figure 59. The differences are more evident at current densities > 7 kA/m^2. The use of baffles on the back of the active surface to enhance the gas lift and aid the supply of brine to the active surface is also common [164].

Flatness is critical for the optimal performance of the anodes in the cells. A typical value < 0.5 mm is achieved, mostly by manual straightening after manufacturing or recoating.

Coating Life. The coating life is determined by a wide range of practical aspects and normally not directly related to the electrochemical wear rate of the coating. These include:

- Mechanical damage to the anode caused by short circuiting [165, 166]
- The need to maintain a recoating schedule, due to production demands and the labor intensive refitting of a cell.
- Synchronization of recoating with the exchange of other consumable parts of the cells such as covers and gaskets.

The tendency has been to increase the lifetime from about 180 t Cl_2/m^2 to 300 – 400 t Cl_2/m^2. This has been achieved by the introduction of better control systems in the cells and the development of intermediate layers of plasma-sprayed conductive TiO_{2-x} between the active coating and the titanium substrate [159].

8.1.3. Anodes for Diaphragm Cells

The predominate determinants in the design of diaphragm anodes are:

- The relatively low current density of ca. 2.0 kA/m^2
- The minimization of the anode – diaphragm gap
- The need to remove and replace the anode array from the cathode, hence the use of retractible anodes

Figure 59. Anode designs for quick gas release
A) Flatt profile (channel blades); B) Rod type (3-, 4-, 5-mm diameter); C) 3D side profile anode

– The limiting height of the cathode, integrated with the diaphragm manufacturing technology

The conventional anodes shown in Figure 60 [167] have been further developed to optimize the energy consumption of the cells by replacing the simple flat expanded metal with complex structures [169]. At present very few plants are still operating without expandable anodes.

Figure 60. Anode for monopolar diaphragm cells
a) Activated (coated) expanded metal; b) Expanding spring; c) Titanium-clad copper bar; d) Copper thread to fix the anode to the cell base

Another type of diaphragm anode is used in the bipolar Ganor cells [168].

Coating Life and Mechanism of Deactivation. The coating lifetime of DSA coatings exceeds 12 years, and production of chlorine exceeds 240 t Cl_2/m^2. The wear is caused by the relatively high oxygen content in a diaphragm cell [170] of ca 1 – 2 %. The wear rate is nonlinear (Fig. 61). This nonlinearity is critical for determining the correct time to begin recoating so as to avoid unplanned stoppages.

8.1.4. Anodes for Membrane Cells

Structure. The variety of designs of membrane cells has led to a range of anodes active area structures; the common principles are the need to support the membrane and gas release to the back of the anode surface. Therefore, thin flattened expanded, perforated metals or louver type structures with and without perforations are used [171].

Figure 61. Empirical fit of observed nonlinear wear rate of coating thickness versus years on line.
$L(t)$ is the loading at time t, L the initial loading, r the wear rate, t time, $A(t)$ the active surface area at time t, q an empirical factor related to the current density sensitivity of the wear rate r

Coating Life. At present the second-generation coatings for membrane cells are showing lifetimes comparable to those of the diaphragm process. The actual lifetime of the anodes is dependent on the extent of damage by caustic flow through holes in the membrane or by contamination with the poisons.

Oxygen Content [151]. The oxygen content has also been improved by the optimization of internal circulation of the brine within the cells.

8.2. Activated Cathode Coatings

Since 1910 diaphragm brine electrolyzers have used carbon steel cathodes and continue to use carbon steel to this day. When the first ion-exchange membrane electrolyzers were introduced in the late 1970s, the cathodes were also carbon steel. By the early 1980s the design had evolved to stainless steel and nickel cathodes, and finally in the 1990s to exclusively nickel cathodes. Depending on current density, the hydrogen overpotential of carbon steel cathodes is about 300 mV. Active cathode coatings can lower the overpotential by 200 – 280 mV, thus providing significant energy savings. Active coatings have often been described in the literature and used in water electrolysis for over 40 years. With the development and evolution of the ion-exchange membrane technology, active cathode coatings are coming into general use.

The patent literature covers many different types of coatings, and new ones are being published regularly. The two basic approaches to activation are high-surface area coatings and catalytic coatings. Both bare nickel and carbon steel show lower hydrogen overpotential once in operation and their surfaces roughen. In fact by grit blasting bare nickel cathodes and roughening the surface, the long-term overpotential can be reduced by 30 – 40 mV. More common are porous nickel-type coatings that offer high surface area and good chemical resistance. These coatings consist of two or more components. At least one of the components is leached out in caustic to leave the porous high surface area nickel [172]. These coatings are typicall nickel-zinc [173], nickel – aluminium – Raney nickel [174], nickel – aluminium [175], or nickel – sulfur [176]. A variety of additives are recommended for strength, life, and resistance to poisoning by impurities. Rough coatings of nickel – nickel oxide mixtures [177] and nickel with embedded activating elements such as ruthenium [178] are also used. Sintered nickel coatings are described in patents [179] as well as being available from Huntington Alloys. Nickel coatings containing platinum group metals, primarily platinum and/or ruthenium, have been sold by Dow [180], Johnson Matthey, and ICI [181].

The coatings used for diaphragm and membrane electrolyzers differ because of the different substrates (carbon steel and nickel, respectively) and the different operating conditions. The weak 11 % caustic in diaphragm cell liquor is less corrosive than the strong 33 % caustic of a membrane electrolyzer. The less expensive and more fragile coatings like nickel – zinc can be used in diaphragm electrolyzers. Membrane electrolyzer suppliers favor the platinum group metal coatings.

The shape of the cathode structure is an important factor affecting the choice of cathode coating. The complex cathodes of diaphragm electrolyzers lend themselves to liquid systems (e.g., electroplating or electroless baths) that can coat the entire structure by immersion [182]. Membrane electrolyzers, which are primarily of a filter-press design, have flat cathodes that are easy to coat by spraying or painting. The lower operating current density of diaphragm electrolyzers means more cathode area per unit of production; this requires a less expensive coating. Most diaphragm electrolyzers use heat-cured polmer – asbestos separators (diaphragms) that are vacuum deposited after the cathode coating is applied. This curing operation can destroy the activity of certain coatings.

All cathode coatings are susceptible to poisoning by impurities that make their way into the catholyte with the deionized water or are components of the piping, electrolyzer etc. These impurities tend to blind the activity of the coatings over a period of time that depends on their concentration. Porous nickel coatings in diaphragm electrolyzers are less susceptible to blinding by impurities because spalling of the brittle coating makes the coatings self-cleaning. The platinum group metal coatings are subject to damage from reverse currents during electrolzer outages. Precautions are needed to protect the coatings with reducing agents [183] or by cathodic protection [184].

Active cathode coating have become the standard throughout the chlor-alkali industry for new construction with the ion-exchange membrane electrolyzer technology. In most of the older diaphragm electrolyzer plants, problems with application of the cathode coatings and generally lower power costs have obviated the use of active cathode coatings. While there are more recent developments applicable to the diaphragm technology in the way of active cathode coatings, many of these developments remain the proprietary information of the technology and coating suppliers.

9. Comparison of the Processes

The advantages and disadvantages of the three chlor-alkali processes are summarized in Table 18. The three chlor-alkali processes can be compared in respect to the quality of the chlorine and caustic produced, and the equipment and operating costs.

Today the membrane process is the state of the art for producing chlorine and sodium hydroxide or potassium hydroxide. All new plants are using this technology. The production capacity of chlor-alkali plants using the membrane process reached about 21 % of total world production capacity in 1995 and is predicted to increase to about 28 % by 2001 (Table 19) [132].

Table 18. Advantages and disadvantages of the three chlor-alkali processes

Process	Advantages	Disadvantages
Diaphragm process	use of well brine, low electrical energy consumption	use of asbestos, high steam consumption for caustic concentration in expensive multistage evaporators, low purity caustic, low chlorine quality, cell sensitivity to pressure variations
Mercury process	50 % caustic direct from cell, high purity chlorine and hydrogen, simple brine purification	use of mercury, use of solid salt, expensive cell operation, costly environmental protection, large floor space
Membrane process	low total energy consumption, low capital investment, inexpensive cell operation, high-purity caustic, insensitivity to cell load variations and shutdowns, further improvements expected	use of solid salt, high purity brine, high oxygen content in chlorine, high cost of membranes

The diaphragm cell capacity remains constant and there is a decline in mercury cell capacity.

Table 19. World chlorine market 1995 and 2001 (in %)

	1995	2001
Diaphragm	52	49
Mercury cell	22	18
Membrane	21	28
Others	5	5
Market, 10^6 t/a	41	43.3

The conditions for a conversion from the mercury and the diaphragm process to the membrane process are discussed below.

9.1. Product Quality

Table 20 shows typical composition values for the chlorine and caustic produced by the diaphragm, mercury, and membrane processes. Chlorine produced by the mercury process can be used directly for most uses. Chlorine produced by the diaphragm or membrane process contains up to 2 % O_2, depending on the pH of the anolyte. This oxygen can be removed by condensation and evaporation of the chlorine.

The sodium hydroxide solution from the mercury process is the purest of the three; the amounts of NaCl and $NaClO_3$ are especially low. However, the quality of caustic from the membrane process is almost as good. A main drawback of the diaphragm process is the high concentration of NaCl and $NaClO_3$ in the caustic solution. This sodium hydroxide solution cannot be used for some processes. A chloride-free grade, commonly referred to as rayon-grade caustic, is required for 20 – 30 % of the demand in industrialized countries. Even the use of purification processes (see page 24) does not reduce the NaCl content below 0.03 wt %. In addition to the NaCl and $NaClO_3$, the levels of Si, Ca, Mg, and sulfate impurities are higher than for the mercury and membrane processes.

9.2. Economics

The wide variation in the main cost factor, that for electrical energy, which varies from region to region by a factor of up to three, makes a direct comparison of production costs problematic. Further, the cost of electrical energy is increasing in different regions at drastically different rates, depending on the basic source of energy and customs. Rapidly changing foreign exchange rates also make international comparisons difficult.

A detailed discussion of the capital investment and operating costs for the three processes for a 200 000 t/a-plant in 1991 is given in [185]. A comparison of the investment costs does not make sense today for the mercury process, because no mercury cell plant and only a few diaphragm cell plants were built since then. All new plants are using the membrane process.

9.2.1. Equipment

The expenses for the rectifier, chlorine and hydrogen systems, HCl system, caustic storage, utilities, and engineering and construction overheads are approximately the same for the three processes.

Table 20. Product qualities: typical compositions of chlorine, caustic, and hydrogen

Product and contents	Process			
	Diaphragm		Mercury	Membrane

* $< 10^{-6}$ %.
** Hydrogen gas from the mercury process contains mercury: 1 μg/m^3 – 10 mg/m^3, depending on the purification process. The hydrogen gas from the other two processes is free of mercury.

Cells. The complex mercury cells are considerably more expensive than the simpler diaphragm and membrane cells. There is no development in mercury cell technology. Improvements are being made in diaphragm cells (higher current densities, longer service times), but the relative advantage of the membrane cells is rising fast with considerable increase in current density and improved membrane performance: Fewer cells are needed for a given production capacity.

Brine System. The brine system for the diaphragm process is the simplest of the three – there is neither sulfate precipitation nor dechlorination – and makes up only 3 – 4 % of the capital investment. The brine system is the most complex for the membrane process, for fine purification by ion exchange is necessary. However, the two- or three-fold greater depletion of the brine in the membrane process allows the brine system to be smaller than that for the mercury process. Therefore, the cost of the brine system for either process is approximately the same, 4 – 7 % of the total.

Caustic Concentration. The elaborate multistage evaporators required for the concentration of the diaphragm-cell caustic and the separation of NaCl and Na_2SO_4 must be nickel plated because of the corrosiveness of the cell liquor containing NaCl and $NaClO_3$. These evaporators cost 20 – 35 % of the total. The evaporators for the membrane process may be constructed of stainless steel and are much smaller because the essentially salt-free cell liquor is more concentrated, costing 3 – 4 % of the total. The mercury process produces 50 % caustic directly, evaporation is not required.

Facilities for Handling Salt. The mercury and membrane plants require storage and handling facilities for solid salt. If a diaphragm plant uses well brine, only small facility is needed for the recycling of the salt from the caustic evaporation.

Mercury. In addition to the capital cost of mercury itself, there is the expense of the equipment to prevent emission of mercury into the environment and to remove mercury from the products (see page 25). This equipment costs 10 – 15 % of the total capital investment.

The investment cost of a new (green-fields) chlor-alkali project in the USA is estimated to be between 250 000 and $ 300 000 per tonne per day chlorine capacity in 1998 [186].

9.2.2. Operating Costs

The fixed costs for operators and other personnel, taxes, insurance, repairs, and maintenance are about the same for all three processes. The 20 % lower depreciation of the membrane process is offset by the additional expense for purchase and replacement of the membranes and for the more elaborate brine purification.

Of the variable costs, the expense for salt, precipitants, and anode reactivation are roughly the same. The difference among the three processes shows up in the consumption of energy, as electricity and steam. If 1 t of steam is taken to be equivalent to 400 kWh of electrical energy, then the comparison in Table 21 can be made. The differing total energy consumptions are illustrated in Figure 62.

Figure 62. Relative consumption of energy (electricity and steam) in the three chlor-alkali processes in producing 50 wt % NaOH

The price of electrical energy varies widely from region to region. The relatively broad range of possible current densities combined with the steep increase in the cell voltage with current density for the diaphragm and membrane cells allows optimization of the current density with respect to the local energy price. That is, if electrical energy is relatively expensive, a greater number of cells, and thus a greater capital investment, can be tolerated to reduce the specific energy consumption and thus minimize total unit production cost [187].

9.2.3. Summary

In spite of the advantages of the membrane technology, about 75 % of all chlorine is produced in mercury and diaphragm cells, operating in ca. 500 plants around the world. Diaphragm technology prevails in the United States (70 %), Russia, and China, and mercury technology in Western Europe (64 %). Continued production from these plants is economical under special circumstances.

For mercury cell users, the question of today is whether the old, depreciated plant is competitive with new membrane cell plants. The alternatives are:

– Further production in the mercury cell plant
– Conversion to the membrane process
– Phasing out the old plant

Candidates for further production are plants of medium to large size, with low electricity costs, with very high quality products, with high emissions standards, with high maintenance standards (low repair costs), or which produce speciality products which cannot be obtained in membrane cells (e.g., alkoxides or dithionites).

All producers that do not fulfill one or more of these conditions are candidates for conversion. The more the existing infrastructure can be used, the greater the benefits resulting from conversion. The investment for the conversion of a middle-sized plant (100 000 t/a) is between $ 550 and $ 800 per tonne of chlorine capacity per year [188]. This investment includes the cost for the membrane cells, secondary brine purification and additional changes of the infrastructure. The costs are specific for each existing plant and depend on:

Table 21. Energy consumed to produce 1 t of chlorine plus 1.13 t of caustic soda (50 %) in the three chlor-alkali processes

Energy	Process		
	Diaphragm	Mercury	Membrane
Electricity for electrolysis, kWh	2300 – 2900	3100 – 3400	2200 – 2600
Steam equivalent, kWh	800 – 1000	0	200 – 400
Total, kWh	3100 – 3900	3100 – 3400	2400 – 3000
Relative energy costs	100 %	93 %	78 %

- Chlorine quality (e.g., the oxygen content)
- The use of existing buildings. The materials of the existing brine treatment area
- The possibility of using the dilute caustic (32 – 36 %) within the plant without concentration
- Use of the existing electrical equipment, rectifiers, busbars
- Possible capacity enlargement because of the lower specific energy per tonne of chlorine
- Dismantling and disposal of mercury-contaminated parts of the old plant.

Normally the decision for a conversion is initiated by plans for an expansion of the production capacity or by environmental legislation. Each change in the plant structure or in the cost structure may lead to reevaluation of the future of the electrolysis plant. Therefore, each plant has to be considered individually [189, 190]. For the European chlor-alkali industry a detailed analysis of the impact of a conversion of all mercury cells to the membrane technology on the competitiveness of the industry is given in [110].

The situation is different for diaphragm cell plants. These plants are still economic where inexpensive brine (e.g., from solution mining) is available, energy costs are comparably low (e.g., from cogeneration of electricity and steam on site), and when the market price for caustic is determined by the lower quality of diaphragm caustic. In countries like the United States it will be difficult to economically justify conversion. In contrast to the mercury process, improvements to the cells are still being made, resulting in lower operating costs and savings in solid waste disposal. The investment to convert a plant with a capacity of 1000 t/d to membrane technology is ca. 90 million dollars [186].

In the first few years after the introduction of membrane technology, diaphragm cells in several plants were equipped with membranes (retrofit) to reduce the cost of steam for cell liquor concentration, to give a small reduction in electricity consumption and better quality of caustic. This procedure is economic where steam is very expensive [187, 191].

10. Other Production Processes

10.1. Electrolysis of Hydrochloric Acid

Electrolytic decomposition of aqueous hydrochloric acid is used to produce chlorine and hydrogen. The first pilot plant was set up by G. Messner in 1942 in Bitterfeld, Germany, and since 1964 eight full-scale plants have been commissioned in Europe and the United States, a total capacity of 540 000 t/a [192]. Hydrogen chloride is a byproduct of many organic industrial processes. Electrolysis of hydrochloric acid competes with chemical processes in which either hydrogen chloride is used to produce chlorinated hydrocarbons directly, e.g., by oxychlorination, or where chlorine is produced by chemical reaction, e.g., in the KEL chlorine process (see page 69). The advantages of the electrolytic process are very pure products without further treatment, reliability (simple design), ease of operation, flexibility (5 : 1 turndown ratio), and low energy consumption even with small installations.

Principles. Hydrochloric acid (22 wt % HCl) is fed into the cells in two separate circuits, a catholyte circuit and an anolyte circuit. During electrolysis the concentration is reduced to ca. 17 %, and the temperature increases from 65 to 80 °C. A part of the depleted acid is separated from the catholyte stream, concentrated in the absorption plant to ca. 30 %, and fed back into the main stream. The electrolyzer is bipolar, with pairs of electrodes arranged like the leaves of a filter press. A diaphragm or membrane (e.g., Nafion 430) separates the anode compartment from the cathode compartment to prevent mixing of the gaseous products.

The reversible standard decomposition potential of hydrochloric acid is 1.358 V, made up of the anode potential, the discharge of chloride ions with formation of chlorine, and the cathode potential, the discharge of hydroxonium (H_3O^+) ions with formation of hydrogen. In practice (> 15 % HCl, 70 °C), the decomposition potential is $\leq$ 1.16 V.

The graphite electrode plates are not attacked by 22 % hydrochloric acid. A poly(vinyl chloride) (PVC) fabric constitutes the diaphragm. Chlorine dissolved in the anolyte diffuses through the diaphragm and is reduced at the cathode, causing a loss of 2 – 2.5 % of the theoretical current yield. The increase of cell voltage when current flows is mainly because of the hydrogen overpotential at the graphite cathode and the resistance of the electrolyte. Depolarizing agents (polyvalent metal ions) in the catholyte reduce the overpotential by $\leq$ 300 mV at 4 kA/m^2 [193].

The conductivity of hydrochloric acid is maximized at a concentration of 18.5 wt %. High temperatures improve the conductivity, but to avoid increased vapor pressure of HCl and material problems, the temperature is kept below 85 °C. Modern cells have a voltage of ca. 1.90 V at 4.8 kA/m^2, corresponding to an energy consumption of 1400 – 1500 kWh per tonne of chlorine.

Diaphragm Cells. Hydrochloric acid electrolysis cells are manufactured by Hoechst – Uhde [194]. Each Hoechst – Uhde electrolyzer consists of 30 – 36 individual cells that are formed from vertical graphite plates connected in series, between which there are diaphragms. To improve gas release, vertical slits are milled in the graphite plates, which are cemented in frames made of HCl-resistant plastics. At the bottom of the frames, channels feed in the electrolyte. The gases rise up the plates and pass through ducts into collection channels in the upper part of the cell. Chlorine leaves the cell with the anolyte, and hydrogen leaves with the catholyte. The end plates of the electrolyzer are made of steel lined internally with rubber and are held together by spring-loaded tension rods. The electric current is supplied via graphite terminals. The unit rests on insulated steel frames. The effective surface of the electrodes is 2.5 m^2, and the current loading can be up to 12 kA.

DeNora and General Electric are developing an electrolyzer with a solid polymer electrolyte (SPE) based on Nafion [195]. In addition to a voltage savings of 20 %, it is hoped that completely chloride-free hydrogen gas can be produced.

Operation. A simplified flow diagram of the process as operated by Bayer – Hoechst – Uhde is shown in Figure 63.

Figure 63. Simplified flow diagram of a hydrochloric acid electrolysis
a) Absorption column; b) Heat exchanger; c) Strong acid tank; d) Catholyte collecting tank; e) Catholyte filter; f) Catholyte supply tank; g) Electrolyzer; h) Hydrogen – catholyte separator; i) Chlorine – anolyte separator; k) Anolyte collecting tank; l) Anolyte filter; m) Anolyte supply tank; n) Weak acid line to absorber

In the absorption column, the hydrogen chloride gas is absorbed adiabatically by depleted hydrochloric acid from the catholyte. In the upper section of the column, an absorber removes the remaining hydrogen chloride and the water vapor by absorption in a water stream, which

makes up the water balance of the process. The 30 wt % acid that is produced is then cooled, purified if necessary by activated carbon, and supplied to the anolyte and catholyte circulation systems.

The electrolyte is pumped through a filter and heat exchanger to a gravity feed tank for the electrolyzer unit. The gases produced are freed from the electrolytes in separators, and the electrolytes flow back into their respective collecting tanks to be resaturated. The working life of the PVC diaphragms, 1 – 2 years, depends on the impurities in the acid. The concentrated acid is, therefore, purified carefully [196].

The product gases are saturated with water vapor and hydrogen chloride at the partial vapor pressures of 20 % hydrochloric acid. Both product streams are cooled. Sodium hydroxide solution is used to wash the hydrogen, removing chlorine and hydrogen chloride and producing a 99.9 % product. The chlorine, which is dried by sulfuric acid, contains ca. 0.5 % hydrogen and ca. 0.05 % carbon dioxide. The hydrogen overpotential can be reduced by activation of the cathodes.

Membrane Cells [197, 198]. Since 1992 Bayer has replaced the woven fabric cloth in the diaphragm cells by anion-exchange membranes of the sulfonate type. Only hydrated protons are able to pass from the anolyte to the catholyte, so that the whole cell and the electrolyte systems are simplified. Together with an optimized surface of the electrodes for better gas release, this leads to:

- Lower cell voltage of 300 mV, corresponding to a power consumption of 1300 kWh per tonne of chlorine at 4.8 kA/m^2
- Longer life of the cell components
- Higher product quality
- Improved safety of operation
- Simplified process

A similar electrolytic process for recovering chlorine from anhydrous HCl, also using membrane cell technology, has been developed by DuPont [199].

10.2. Chemical Processes

The chlor-alkali process produces chlorine and sodium hydroxide solution in fixed stoichiometric proportions. Experience has shown that there tends to be a surplus of either chlorine or sodium hydroxide. Chlorine may, however, be produced competitively without the byproduct sodium hydroxide by nonelectrolytic methods. The starting material is usually hydrogen chloride, which is catalytically oxidized to chlorine by oxygen, air, nitric acid, sulfur trioxide, or hydrogen peroxide. Other processes start from ammonium chloride or metal chlorides.

10.2.1. Catalytic Oxidation of Hydrogen Chloride by Oxygen

A catalyst is essential for the economic oxidation of hydrogen chloride to chlorine by air or oxygen (Deacon Process), and the catalyst must be active at low temperature and have adequate life. There are many patents claiming improved catalysts and equipment. Most of the catalysts are oxides and/or chlorides of metals on various substrates. Only three processes have been commercialized.

The KEL Chlorine Process. The process developed by Kellogg [197] uses concentrated sulfuric acid (ca. 80 %) with ca. 1 % nitrosylsulfuric acid as the catalyst. From 1975 to 1988 Du Pont operated a full-scale plant in Corpus Christi, Texas, recovering up to 600 t/d of chlorine. The plant was shut down due to a change in the structure of the plant and because of material problems after more than 10 years of operation. The raw material, from a fluorinated hydrocarbon plant, consisted of waste gases that contained hydrogen chloride [200]. Figure 64 shows a simplified flow diagram.

Sulfuric acid catalyst is fed into the top of the stripper column. The hydrogen chloride gas reacts with the catalyst to form nitrosyl chloride:

$$HCl + NOHSO_4 \rightarrow NOCl + H_2SO_4$$

The oxygen, the ultimate oxidizing agent, blows the remaining hydrogen chloride out of the sulfuric acid, which becomes more concentrated and also is cooled in a flash vaporizer. This acid is then fed back into the process. Nitrosyl chloride, hydrogen chloride, oxygen, and water

vapor flow as a gaseous stream into the oxidizer and react there, increasing the temperature:

$$2\,NOCl + O_2 \rightarrow 2\,NO_2 + Cl_2$$

$$NO_2 + 2\,HCl \rightarrow NO + Cl_2 + H_2O$$

In the absorber – oxidizer, the rest of the hydrogen chloride is oxidized. Concentrated sulfuric acid is fed in at the top, reacts with the oxides of nitrogen to form nitrosylsulfuric acid, absorbs the water that has formed, and is conducted back into the stripper:

$$NO + NO_2 + 2\,H_2SO_4 \rightarrow 2\,NOHSO_4 + H_2O$$

$$NOCl + H_2SO_4 \rightarrow NOHSO_4 + HCl$$

Figure 64. Flow diagram of the KEL chlorine process (simplified)
a) Stripper; b) Oxidizer; c) Absorber – oxidizer; d) Acid chiller; e) Acid cooler; f) Vacuum flash evaporator

The cooled, dried chlorine gas still contains ca. 2 % hydrogen chloride and up to 10 % oxygen. Both are removed by liquefaction.

The net reaction is

$$4\,HCl + O_2 \rightarrow 2\,Cl_2 + 2\,H_2O$$

The installation at Corpus Christi operated at 1.4 MPa and 120 – 180 °C. On account of the aggressive nature of the chemicals, expensive materials, such as tantalum-plated equipment and pipes, must be used. For outputs of 250 – 300 t of chlorine per day, this process can be more economical than the electrolysis of hydrochloric acid, depending on local conditions.

The Shell Chlorine Process. The catalyst developed by Shell consists of a mixture of copper(II) chloride and other metallic chlorides on a silicate carrier [201]. The reaction of the stoichiometric mixture of hydrogen chloride and air takes place in a fluidized-bed reactor at ca. 365 °C and 0.1 – 0.2 MPa. The yield is 75 %. The water condenses out from the gas stream, and the hydrogen chloride is removed by washing with dilute hydrochloric acid. After the residual gas has been dried with concentrated sulfuric acid, the chlorine is selectively absorbed, e.g., by disulfur dichloride. After desorption and liquefaction, the chlorine has a purity > 99.95 %.

A manufacturing unit was built by Shell in the Netherlands, 41 000 t/a, and another in India, 27 000 t/a, but both have been closed down owing to the prolonged surplus of chlorine on the market.

The Mitsui MT-Chlorine Process. The catalyst consists of chromium(III) oxide on a silicate carrier [202]. In a fluidized-bed reactor, hydrogen chloride is reacted with oxygen at a temperature of 415 °C to give chlorine gas with a conversion rate of 73 – 77 %. The reactor is made from nickel-lined low carbon steel. The concentration of the purified product is > 99.5 % Cl_2.

A commercial plant for 30 000 t Cl_2/a is successfully operating since 1988, with an expansion to 60 000 t Cl_2/a in 1990.

A two-stage cyclic fluidized bed process for converting HCl to chlorine is described in [203]. The catalytic oxidation process combines the exothermic oxidation of 60 – 70 % of the HCl at 380 – 400 °C in a fluidized bed of copper oxychlorides impregnated on zeolite with the transfer of the reaction products to a second reactor operating at 180 – 200 °C where the rest of HCl is converted.

10.2.2. Oxidation of Hydrogen Chloride by Nitric Acid

The nitrosyl chloride route to chlorine is based on the strongly oxidizing properties of nitric acid:

$$6\,HCl + 2\,HNO_3 \rightarrow 2\,Cl_2 + 2\,NOCl + 4\,H_2O$$

$$2\,NOCl + 2\,H_2O + O_2 \rightarrow 2\,HCl + 2\,HNO_3$$

The practical problems lie in the separation of the chlorine from the hydrogen chloride and nitrous gases. The dilute nitric acid must be reconcentrated. Corrosion problems are severe. Suggested improvements include (1) oxidation of concentrated solutions of chlorides, e.g., LiCl, by nitrates followed by separation of chlorine from nitrosyl chloride by distillation at 135 °C or (2) oxidation by a mixture of nitric and sulfuric acids with separation of the product chlorine and nitrogen dioxide by liquefaction and fractional distillation [204].

10.2.3. Production of Chlorine from Chlorides

Alkali-metal chlorides, ammonium chloride, and other metallic chlorides are reacted, usually with nitric acid, to produce nitrate fertilizers [205]. Chlorine is not produced directly, but it can be obtained from the intermediate products nitrosyl chloride or hydrochloric acid.

11. Chlorine Purification and Liquefaction

Chlorine produced by the various processes, especially by electrolysis, is saturated with water vapor at high temperature and may also contain brine mist and traces of chlorinated hydrocarbons, and is normally at atmospheric pressure. Before the chlorine can be used, it must be cooled, dried, purified, compressed, and where necessary, liquefied. A simplified flow sheet is shown in Figure 65.

11.1. Cooling

Table 22 shows the volume, water content, and heat content of 1 kg of chlorine gas at 101.3 kPa as a function of temperature. To avoid solid chlorine hydrate formation, the gas is not cooled below 10 °C [206]. Cooling is accomplished in either one stage with chilled water or in two stages with chilled water only in the second stage.

Table 22. Volume, moisture content, and enthalpy of 1 kg of chlorine gas at 101.3 kPa as a function of temperature *t*

t, °C	Volume, m^3		Water content, g/kg **	Heat content, kJ/kg *
	Dry	Saturated *		
0	0.312	0.314	1.54	3.81
20	0.335	0.342	5.95	24.45
40	0.357	0.385		69.50
			19.7	
60	0.380	0.473	61.5	188.41
70	0.392	0.565	112.0	325.73
80	0.404	0.756	222.0	623.83

* Chlorine gas saturated with water vapor at temperature *t*.
** Grams of H_2O per kg of Cl_2.

The chlorine gas can be *cooled indirectly* in a tubular titanium heat exchanger so that the cooling water is not contaminated and the pressure drop is small. The resultant condensate is either fed back into the brine system of the mercury process or dechlorinated by evaporation in the case of the diaphragm process.

The chlorine gas can be *cooled directly* in packed towers. Water is sprayed into the top and flows countercurrent to the chlorine. This treatment thoroughly washes the chlorine; however, dechlorination of the wastewater consumes a large amount of energy. The cooling water should be free of traces of ammonium salts to avoid the formation of nitrogen trichloride.

Closed-circuit direct cooling of chlorine combines the advantages of the two methods.

Figure 65. Simplified flow diagram of a chlorine processing plant
a) Chlorine gas cooler (primary); b) Chlorine demister; c) Blower or fan; d) Chlorine gas cooler/chiller (secondary); e) Condensate collection tank; f) Drier, first stage; g) Drier, second stage; h) Sulfuric acid mist separator; i) Sulfuric acid circulation pump; k) Cooler for circulating sulfuric acid; l) Sulfuric acid feed tank; m) Cooler for sulfuric acid feed

The chlorine-laden water from the cooling tower is cooled in titanium plate coolers and recycled. The surplus condensate is treated like the condensate from indirect cooling. Spray towers, as well as packed towers, are used. Water carryover is removed by demisters, which reduce the amount of sulfuric acid used for drying.

11.2. Chlorine Purification

Water droplets and impurities such as brine mist are mechanically removed by special filter elements with glass wool fillings. The efficiency varies with the gas throughput. A commonly used device is the Brink *demister* [207]. Instead of glass wool, porous quartz granules can be used.

In *electrostatic purification,* the wet chlorine gas is passed between wire electrodes in vertical tubes. The electrodes are maintained at a d.c. potential of 50 kV with a current density of 0.2 mA/m^2. The particles and droplets in the chlorine become charged and collect on the tube walls. The resultant liquid is fed back into the brine system or chemically treated before disposal.

Activated carbon filters can adsorb organic impurities and may be regenerated by heating to 200 °C.

Gaseous impurities can be removed by *absorption* of the chlorine in a suitable solvent, such as carbon tetrachloride, water, or disulfur dichloride, followed by *desorption.* This can be coupled with further processes, such as the recovery of chlorine from the waste gas remaining after liquefaction [15, pp. 418 – 422].

A wash with concentrated hydrochloric acid removes the dangerously explosive nitrogen trichloride [208]. *Scrubbing with liquid chlorine* (see Fig. 67) mainly reduces the content of organic impurities and carbon dioxide, but it can also lower the bromine content. When the chlorine is cooled down to near its dew point, liquid chlorine scrubbing is often combined with compression by turbo or reciprocating compressors.

11.3. Drying

Drying of chlorine is carried out almost exclusively with concentrated sulfuric acid (96 – 98 wt %) [209]. Depending on the desired final concentration of the waste acid, drying can be a two-, three-, or four-stage process. The acid and chlorine flow countercurrently. The fi-

nal moisture content depends on the concentration and temperature of the acid in the final stage (Fig. 66). An upper limit is 50 ppm H_2O. Low-temperature liquefaction (−70 °C) demands lower moisture content, which can be achieved with molecular sieves, whereby 2.5 ppm is possible [210].

Figure 66. Drying chlorine with sulfuric acid
Attainable moisture content as a function of concentration and temperature of the acid

The *packed towers* usual in the first stages are constructed of rubber-lined steel or glass-fiber-reinforced poly(vinyl chloride). The heat liberated on dilution of the circulating acid is removed by titanium heat exchangers, and the weak acid is dechlorinated chemically or by blowing air. Often the acid is recirculated after reconcentration to 96 % by heating under vacuum. Generally, columns with *bubble cap plates* or *sieve trays* are used at the final stage. The drying is effective, but the pressure drop is great. Occasionally, spray towers are used to dry chlorine.

After drying, the chlorine gas is passed through a demister or a packed bed to remove sulfuric acid mist.

11.4. Transfer and Compression

In all operations involving compression, care must be exercised to prevent the heat of compression from increasing the temperature enough to ignite material in contact with the chlorine.

Wet chlorine gas can be compressed 20–50 kPa by a single-stage *blower* or *fan* with a rubber-lined steel casing and titanium impeller. It can also be compressed in *liquid-ring compressors,* so that further treatment of the chlorine can be accomplished in smaller equipment [211]. Sulfuric acid ring compressors are used for throughputs of 150 t of dry chlorine gas per day per compressor and for pressures of 0.4 MPa or, in two-stage compressors, 1.2 MPa. The heat of compression is removed by cooling the circulating liquid; cooling of the gas is not necessary. Advantages are simplicity of construction, strength, and reliability, but efficiency is low [212].

Reciprocating compressors were formerly lubricated with sulfuric acid, but are now available as *dry-ring compressors* (no lubrication). They can compress up to 200 t per day. Multistage compressors produce pressures up to 1.6 MPa. The heat of compression of each stage must be removed by heat exchangers or by injection of liquid chlorine (see Fig. 67). Well-purified chlorine gas is essential for trouble-free operation [213].

Figure 67. Multistage reciprocating compressor for chlorine liquefaction at 1 MPa with cooling water at 15 °C with liquid chlorine scrubbing
a) Low-temperature cooling and scrubbing column; b) Collection tank for impurities; c) Three-stage compressor; d) Intermediate cooler, stage 1; e) Intermediate cooler, stage 2; f) Liquefier; g) Chlorine collection vessel; h) Chlorine storage tank; i) Chlorine storage tank on load cells

Turbo compressors are most economical when they operate with large amounts of chlorine. Each unit compresses up to 1800 t/d. In multiple-stage operation, pressures up to

1.6 MPa are reached. Labyrinth seals are used on the high-speed shafts. Requirements for cooling and gas purity are like those of reciprocating compressors. *Screw compressors* handle low rates of chlorine and give pressures up to 0.6 MPa. *Sundyne blowers* are one-stage high-speed centrifugal compressors handling 80 – 250 t per day and giving pressures up to 0.3 MPa. Liquid chlorine injection is used for cooling [214]. *Membrane compressors* are used for pressurizing storage tanks with chlorine gas to transfer liquid chlorine to other vessels [215]. Liquid chlorine is pumped with *canned pumps* [216].

11.5. Liquefaction

The most suitable liquefaction conditions can be selected within wide limits. Important factors are the composition of the chlorine gas, the desired purity of the liquid chlorine, and the desired yield. There are nomograms that give the relationship between the chlorine concentrations of the incoming and residual gases, liquefaction yields, pressures, and temperatures [217]. Increasing the liquefaction pressure increases the energy cost of chlorine compression, although the necessary amount of cooling decreases, resulting in an overall reduction in energy requirement (Table 23) [218].

Table 23. Electrical energy requirement for compression and liquefaction of 1 t of chlorine gas

	Liquefaction pressure, MPa			
	0.1	0.3	0.8	1.6
Energy for compression, kWh/t	5	23	42	57
Energy for cooling, kWh/t	87	68	27	3
Combined energy, kWh/t	*92*	*91*	*69*	*60*
Starting temperature, °C	−36	−8	25	53
Final temperature, °C	−42	−17	14	40

Any hydrogen is concentrated in the residual gas. To keep the hydrogen concentration below the 6 % explosive limit, conversion of gas to liquid should be limited to 90 – 95 % in a single-stage installation. Higher yields may be obtained by condensing the chlorine from the residual gas in a second stage, which is constructed to reduce the risk from explosion [219]. This is achieved by the use of sufficiently strong equipment to withstand explosions or by the addition of enough inert gas to keep the mixture below the explosive limit. Multistage installations can liquefy over 99.8 % of the chlorine gas.

High-pressure (0.7 – 1.6 MPa) liquefaction with *water cooling* (Fig. 67) does not require a cooling plant. Therefore, it has the lowest energy cost of all methods; however, the high construction cost must be set against this.

Medium-pressure (0.2 – 0.6 MPa) liquefaction with *cooling* (− 10 to − 20 °C) is especially useful when only a part of the chlorine is to be liquefied and the remaining gas is to be reacted at the liquefaction pressure, e.g., with ethylene to form ethylene dichloride. The residual gas can be fed into the compressor suction systems, provided that the increased inert gas content does not interfere with the subsequent process. Otherwise, the residual gas must be scrubbed free of chlorine or liquefied in a second stage.

Figure 68 shows a two-stage liquefaction by the Uhde system, which operates at 0.3 – 0.4 MPa and − 20 °C in the first stage and − 60 °C in the second stage, with a yield of 99 % [220]. The refrigerant is difluoromonochloromethane. The gaseous refrigerant is compressed, liquefied by water cooling, and collected in a container. The liquid refrigerant is sprayed into the shell of the chlorine liquefier, where it evaporates, absorbing heat and cooling the chlorine, which flows from the liquefiers at − 15 °C (first liquefier) or − 55 °C (second liquefier) [221]. The residual gas from the first horizontal liquefier contains < 5 % hydrogen. It is fed into the second liquefier, which is at an angle of 60° and has a strong, low-volume construction. There the gas mixture passes through the explosive concentration limits. In case of an explosion, there is a comprehensive control system to ensure safety:

The explosion pressure is vented by means of a bursting disk to a residual gas absorber. Simultaneously the residual gas from the first stage is passed directly into this absorber. The chlorine gas to the second stage is shut off, and an inert gas purge is introduced. Finally, the liquid chlorine exit valve is closed to prevent back flow of the liquid chlorine into the second liquefier and from there into the absorber.

With normal-pressure (ca. 0.1 MPa) liquefaction and *low temperature* (< − 40 °C), cryogenic storage of the liquid chlorine is possible.

Figure 68. Flow diagram of a two-stage chlorine liquefaction plant at intermediate pressure – Uhde system

This process is advantageous when large quantities of chlorine must be liquefied as completely as possible. Attention must be paid to the increased solubility of other gases at low temperatures, especially carbon dioxide [206]. This carbon dioxide can be removed from the liquid chlorine by passage of hot chlorine gas [219].

An *absorption – desorption process* by Akzo is based on carbon tetrachloride [222]. It requires little energy and yields over 99.8 % of a pure liquid chlorine that is almost free of carbon dioxide. A similar process by Diamond Shamrock has been described [224].

11.6. Chlorine Recovery

Chlorine can be recovered from the tail gas from liquefaction with a chlorine recovery system.

Tail gas from liquefaction and chlorine from the plant evacuation system together with the snift compressor and stripper recycle streams are supplied to a snift compressor suction knockout drum. The gas is compressed by the snift gas compressor to 7.0 kg/cm^2 with a discharge temperature of 85 °C.

The snift gas is then cooled by cooling water to 45 °C and then further cooled to − 12.2 °C by Freon. Gas is sent to the absorber, whereas liquid is either returned to chlorine storage or is used for reflux at the stripper.

The off-gas enters the bottom of the chlorine absorber and passes upward through the two packed sections of the tower while cold carbon tetrachloride flows downward. All of the chlorine and the nitrogen trichloride is absorbed in the carbon tetrachloride while the noncondensable gases remain in the gasphase and are removed from the system.

The chlorine-rich carbon tetrachloride leaves the bottom of the chlorine absorber at ca. 10 °C and is forced by pressure difference to the chlorine stripper. Chlorine stripper feed enters the middle of the column and flows downward through two packed sections, releasing chlorine as it is heated. A thermosiphon reboiler is provided at the base of the stripper. By heating the liquid above 65 °C, the absorbed nitrogen trichloride decomposes to nitrogen and chlorine gas.

Chlorine boiled off in the stripper passes upward through a packed top section of the column where it is scrubbed and purified by liq-

uid chlorine from the discharge knock-out drum. The stripper overhead stream, a mixture of chlorine and a small amount of inerts, is sent to the chlorine liquefaction system or recycled to the suction knock-out drum to maintain the stripper reflux [222, 223].

12. Chlorine Handling

Both the chlorine industry and governmental organizations are well aware of the risks of chlorine. In the United States and Canada, The Chlorine Institute [225] has established standards and recommendations for safe transport and handling of chlorine since 1924. In Europe, Euro Chlor, an association of major Western European chlorine manufacturers, publishes recommendations, codes, and memorandums for chlorine handling and transport concerning European conditions and regulations [226]. Both organizations distribute manuals and pamphlets worldwide. Surveys of existing national and international regulations for the handling and transport of hazardous chemicals are available [2, 34, 227, 229].

12.1. Storage Systems

Chlorine is liquified and stored at ambient or low temperature [230, 233]. In both cases the pressure in the storage system corresponds to the vapor pressure of liquefied chlorine at the temperature in the stock tank. *Pressure storage* is recommended for all usual customers [234, 235]. Euro Chlor recommends a maximum capacity of 300 – 400 t for individual tanks. For the large storage capacities required by producers, usually a *low-pressure storage* system, operating at a liquid chlorine temperature of ca. – 34 °C, is chosen. A low-pressure system needs a cooling or recompression system, and, for this reason, it is basically unsuitable for small chlorine consumers [236, 237].

A few major design aspects must be mentioned. Any risk of fire or explosion must be eliminated. All tanks having an external connection below the liquid level should be placed in a liquor-tight embankment (bund). In the event of leakage the liquid should be collected in a small area to reduce the rate of vaporization. The outer shell around a double-enveloped low-pressure storage tank can provide such a facility. To vent chlorine, there must be an absorption or liquefaction system. In the course of all operations, the design pressure should not be exceeded. The dimensions of branches and the amount of pipe work should be minimized. Bottom connections from storage tanks are not recommended for small chlorine users. Large branches should always be located in the gas space of a vessel. The pipework system should be provided with remotely operable valves to permit isolation in case of emergency.

Before being put into service, the whole storage system must be degreased, cleaned, and dried to achieve a dew point of – 40 °C in the purge gas at the outlet of the system. No substance that could react with the chlorine can be allowed to enter the storage system. The filling ratio in the tank should never exceed 95 % of the total volume of the vessel; for pressure storage tanks, this corresponds to 1.25 kg of liquid chlorine per liter of vessel capacity at 50 °C (Fig. 69).

Figure 69. Proportion (%) of a one-liter vessel occupied by 1.25 kg of liquid chlorine as a function of temperature

Typical measuring and control equipment of a pressure storage tank is shown in Figure 70. The ISO codes for process measurement control functions and instrumentation are explained in Table 24 [238]. The measuring equipment of a low-pressure storage system needs supplementary devices, for example, a temperature indicator with an alarm and, in the case of a double-

shell vessel, a device to determine the quality of the purging gas inside the double shell. The vessel and an external envelope should be protected against overpressure or underpressure. In low-pressure systems, the chlorine is removed by vertical submerged pumps, canned pumps below the vessel, or ejector pumps operating with a flow of liquid chlorine produced by external pumps.

Table 24. ISO codes and miscellaneous symbols for process measurement control functions and instrumentation

Codes	Function or Instrumentation
AA	analysis alarm
CW	cooling water
dPI	difference pressure indicating
FA	flowrate alarm
FI	flowrate indicating
FIA	flowrate indicating alarm
FICA	flowrate indicating controlling alarm
FRA	flowrate recording alarm
HZ	hand operated emergency acting
H	high
L	low
LA	level alarm
LIA	level indicating alarm
LIC	level indicating controlling
M	moisture analysis
PA	pressure alarm
PCZA	pressure controlling emergency acting alarm
PI	pressure indicating
PIA	pressure indicating alarm
PIAS	pressure indicating alarm switching
PIC	pressure indicating controlling
PRC	pressure recording controlling
PSA	pressure switching alarm

WIA	weight indicating alarm
⬭	measuring device
⧖	remote control valve
– – –	control line

Periodic inspection and retesting of the whole system, including a visual examination, a thickness test of the wall of the vessel and pipes, and an examination of the welds and the surfaces under any thermal insulation, is recommended. Hydraulic retesting is accompanied by risk of corrosion and is, therefore, not favored.

12.2. Transport

Within a chemical plant and over distances of several kilometers, chlorine can be transported by pipelines, either as gas or liquid [24, 239]. Every precaution should be taken to avoid any vaporization of chlorine in a liquid-phase system or any condensation in a gas-phase system. Wherever liquid chlorine could be trapped between two closed valves or wherever the system could be overpressurized by thermal expansion, an expansion chamber, a relief valve, or a rupture disk should be provided [240, 241].

Commercial chlorine is transported as a liquid, either in small containers (cylinders and drums) or in bulk (road and rail tankers, barges, and ISO containers). The design, construction, system of labeling, inspection, and commissioning are covered by national and international regulations [227]. *Cylinders* have a chlorine content up to 70 kg. A protective hood is provided to cover the valve during transport. The ton containers (drums) have a capacity of 500 – 3000 kg of chlorine. Drums are equipped with two valves near the center of one end and connected with internal eductor pipes.

The capacity of *tank cars* (rail tankers) ranges from 15 to 90 t. Special angle valves are mounted on the manhole cover on top of the vessel. In Europe, pneumatic valves are normally used [230 – 232]. During loading and unloading, these valves can be closed rapidly and remotely in case of an accident. They have an internal safety plug, providing a tight seal against the passage of gas or liquid chlorine in the event of failure of the body of the valve.

In North America, the eductor pipe inside the vessel has an excess-flow valve at the top, immediately below the manhole cover. This valve closes the eductor pipe when the rate of liquid flow exceeds a set rate [2, 24]. North American tank cars have a spring-loaded safety relief valve, which protects the vessel against overpressure in case of external heat. The tanks have thermal insulation. In Europe thermal insulation and safety relief valves are not used or recommended.

Road tankers and ISO containers have a chlorine capacity of 15 – 20 t. The design of and the equipment on chlorine pressure road tankers is similar to these of rail tankers. In North America, large amounts of chlorine are transported by

Figure 70. Discharge of liquid chlorine by padding to pressure storage

tank barges [24]. These barges usually are of the open-hopper type with several cylindrical uninsulated pressure vessels. The total capacity of barges ranges from 600 to 1200 t. The chlorine is transported at low temperature.

Classification and Labeling. According to Directive EEC 67/548, Annex I, chlorine (Index no. 017–001–00–7) is classified as toxic and dangerous to the environment. The R and S phrases are:

R 23	toxic by inhalation
R 36/37/38	irritating to eyes, respiratory system and skin
R 50	very toxic to aquatic organisms
S 7/9	keep container tightly closed and in a well-ventilated place

For transportation, chlorine is in class 2, no. 2TC (toxic, corrosive) in ADR, RID, and ADNR in Europe, and in class 2.3 in the IMDG Code (p. 2116) and ICAO Code. All vessels must be labeled with the denomination 268/1017 Chlorine and with labels for dangerous goods: cylinders and drums with labels 2.3 (toxic gas) and 8 (corrosive); railroad tankers with labels 2.3, 8, and 13 (shunt carefully); and for shipping, labels 2.3, 8, and MP (marine pollutant).

12.3. Chlorine Discharge Systems

All containers should be discharged in the same order as received. They must be placed where any external corrosion, risk of fire, explosion, or damage is avoided [24]. At normal room temperature, the discharge rate of chlorine gas from a single 70-kg cylinder is ca. 5 kg/h and the rate of a drum is ca. 50 kg/h. The flow of chlorine gas can be increased by a higher ambient temperature or by connecting two or more containers. A system of two or more containers must be carefully operated and controlled to avoid overfilling by transfer of chlorine from warm to cool containers. Direct heating of containers is not recommended [24]. The best way to determine the flow rate and container content is to observe the weight of the container [228]. A flexible tube is used to connect a mobile container with the fixed piping system. Any reverse suction from the consuming plant must be prevented by a barometric leg or other adequate precaution if the chlorination process runs at atmospheric pressure. Pressurized processes need a pressure controlling system with automatic isolation valves.

Uninsulated tanks have a maximum gaseous discharge rate of ca. 2 t/h. The chlorine gas can be used only for low-pressure chlorination processes and at low rates. This method increases

Figure 71. Liquid chlorine vaporizer

the risk of concentrating nitrogen trichloride and other nonvolatile residues in the liquid phase within the tank. In all other circumstances, the liquid chlorine should be transferred into a fixed storage vessel and then vaporized in a special installation.

Liquid chlorine is discharged by putting the tank under pressure with dry inert gas or dry chlorine gas. The inert transfer gas must have a dew point below $-40\,^{\circ}C$ at atmospheric pressure and must be clean and free of impurities such as dust or oil. Before closing the valves, the tanks must be vented to avoid the risk of high pressure in the container on account of the additional partial pressure of the inert gas. The use of an inert gas requires the availability of a chlorine absorption or neutralization system. Discharge with pressurized chlorine gas requires a chlorine vaporizer or a special chlorine compressor. Articulated arms, flexible hoses, and steel coils are used for the flexible connections. Remote-control valves installed close to the ends of the flexible connections limit leakage in the event of a failure.

Recommendations on technical equipment, installation, taking into operation, checks, and handling are provided by The Chlorine Institute and Euro Chlor.

12.4. Chlorine Vaporization

When large amounts of chlorine gas are required or when the chlorination process needs pressurized gas, liquid chlorine must be vaporized and superheated to avoid liquefaction [242, 243]. It is advisable to operate the vaporizer at a sufficiently high temperature to accelerate the decomposition of nitrogen trichloride. As a source of heat, steam with a maximum allowed temperature of $120\,^{\circ}C$ is used when the vaporizing system is constructed of mild steel. Water above $60\,^{\circ}C$ is also suitable, as shown in Figure 71. Direct electrical heating is not appropriate because there is always a risk of overheating the steel.

Coil-in-bath vaporizers use a coiled tube or a spiral located in a vessel of hot water (Fig. 71). Generally, they are used for small throughputs; they are simple in design and construction. Double-envelope vaporizers have compact construction and are easy to operate and to maintain. Vertical tube vaporizers have a large surface area and allow a high flow rate. Kettle vaporizers are also constructed for large unit capacities [244]. Every effort must be taken to avoid the reverse suction of water or organic materials into the vaporizer. The recommended water and nitrogen trichloride content of introduced liquid chlorine must not be exceeded. Vaporizers operating at low temperature or with a constant liquid level

Figure 72. Absorption equipment for the treatment of gases containing chlorine
a) Buffer vessel; b) Vent fan; c) Packed tower; d) Circulating pump; e) Heat exchanger (cooler)

need to be purged to avoid dangerous concentration of nitrogen trichloride [245, 246].

12.5. Treatment of Gaseous Effluents

Gaseous effluents containing chlorine arise from various sources and must be treated in such a way as to obtain a tolerable concentration of chlorine when they are released into the air. The vent gas may contain other substances, such as hydrogen, organic compounds, CO_2, etc., which must be considered in design and operation of an effluent treatment installation [247, 248].

Operation of the collection system below atmospheric pressure facilitates the purging of chlorine vessels, pipes, etc. The risk of corrosion in dry chlorine installations by moisture from the treatment system must be excluded. The most commonly used and recommended reagent is caustic soda. The effluents are treated in an absorption system, such as packed absorption towers, venturi scrubbers, etc. An example of a flow sheet for a large plant is shown in Figure 72.

To avoid any formation of solid salts, the recommended concentration of caustic soda is < 22 wt %. The operating temperature should not exceed 55 °C; under normal conditions a temperature of ca. 45 °C is usual. A cooling system may be necessary. In large chlorine absorption units, the sodium hypochlorite solution that is produced can be used in other processes. Where this is not possible, several methods can be used to decompose the hypochlorite: controlled thermal decomposition, catalytic decomposition [249], acidification, for example, with sulfuric acid

$$NaCl + NaOCl + H_2SO_4 \rightarrow Na_2SO_4 + Cl_2 + H_2O$$

12.6. Materials

The choice of material [250] depends on the design and operating conditions and must take into account all circumstances. A chlorine manufacturer should be consulted to confirm the suitability of a material. Any use of silicone materials in chlorine equipment should be avoided.

Dry Chlorine Gas (water < 40 ppm by weight). Carbon steel is the material most used for dry chlorine gas. It is protected by a thin layer of ferric chloride. For practical purposes the recommended temperature of these materials is ≤ 120 °C. High-surface areas, such as steel wool, or the presence of rust and organic substances increase the risk of ignition of steel.

The resistance of stainless steels to chlorine at high temperature increases with the content of nickel. For stainless steels containing less than 10 wt % nickel, the upper temperature limit is

150 °C. High-nickel alloys, such as Monel, Inconel, or Hasteloy C, are suitable up to 350–500 °C. Poor mechanical strength limits the use of nickel. Copper is used for flexible connections and coils, but it becomes brittle when stressed frequently.

Because titanium ignites spontaneously in dry chlorine, it must be avoided. Graphite, glass, and glazed porcelain are used where there is a risk of moisture in the dry chlorine gas, and poly(vinyl chloride) (PVC) or chlorinated PVC and polyester resins are suitable if the temperature limits of these materials are regarded.

Liquid Chlorine. Unalloyed carbon steel and cast steel are used with liquid chlorine. Low-temperature chlorine systems apply fine-grain steels with a limited tensile strength to guarantee good conditions for welding. To avoid erosion of the protective layer, practice is to limit the velocity of the liquid to less than 2 m/s. Organic materials – rubber lining, ebonites, polyethylene, polypropylene, PVC, chlorinated PVC, polyester resins, and silicone – are dangerous [251]. Zinc, tin, aluminum, and titanium are not acceptable. For certain equipment, copper, silver, lead, and tantalum are appropriate.

Wet Chlorine Gas. Wet chlorine gas rapidly attacks most common metallic materials with the exception of tantalum and titanium. To assure a protective oxide layer on the surface of the titanium, sufficient water must be present in the chlorine gas. If the system does not remain sufficiently wet, titanium ignites spontaneously [252].

Most organic materials are slowly attacked by wet chlorine gas. Rubber-lined iron is successfully used up to 100 °C. At low pressure and temperature the use of plastic materials like PVC, chlorinated PVC, and reinforced polyester resins is advantageous. Polytetrafluoroethylene (PTFE), poly(vinylidene fluoride) (PVDF), and fluorinated copolymers like tetrafluoroethylene – hexafluoropropylene (FEP) are resistant even at higher temperature. Ceramics have been progressively replaced by plastics. Impregnated graphite is suitable up to 80 °C; the impregnation should be resistant to wet chlorine.

Materials for Special Parts. After the ban of asbestos as material for gaskets, substitutes are recommended [253]. In wet chlorine gas, rubber or synthetic elastomers are acceptable. Even at temperatures up to 200 °C, PTFE is resistant against wet and dry chlorine gas and liquid chlorine.

Materials resistant because of protection by a chloride surface layer are not recommended for protective membranes, rupture disks, and bellows. Suitable materials are tantalum, Hasteloy C, PTFE, PVDF, Monel, and nickel.

12.7. Safety

In hazard and risk assessment studies, the design of chlorine installations and equipment and the operating and maintenance concepts are examined in detail to minimize risks [254]. However, there remains a certain risk, and all efforts must be taken to protect people and the environment in the case of a chlorine emergency. The penetrating odor and the yellow-green color of a cloud indicate chlorine in the air. If around-the-clock surveillance by operators is not possible, automatic leak detectors are available. Safety in handling chlorine depends largely on the education and training of employees. An emergency plan should be brought to the attention of the personnel involved. Computer-assisted systems can be used in certain circumstances [255]. Periodic exercises and safety drills should be carried out.

All people on a chlorine plant are advised to carry escape-type respirators. The use of filter masks is prohibited where there is a risk of a high concentration of chlorine. Anyone who enters an area with high chlorine concentrations should be equipped with self-contained breathing apparatus and full protective clothing suitable for dealing with liquid chlorine. Protective equipment, safety showers, eye-wash facilities, and emergency kits [24] must be quickly accessible.

A means of indicating the actual wind direction should be located near the chlorine installation.

Fixed or mobile water curtains can be used to divert the dispersion of a chlorine gas cloud [256]. However, the direct discharge of water into liquid chlorine and on the area of a chlorine leak must be avoided.

In most countries, chlorine manufacturers have organized groups of experts who are well versed and drilled in handling chlorine and can be called at any time in case of chlorine emergency.

The Chlorine Institute has released pamphlets and recommendations covering all aspects of safety, e.g., first aid [257], emergency response plans [258], protective equipment [259], prevention of injuries to personnel [260], prevention of chlorine releases [261], and estimating the area affected by a chlorine release [262]. Emergency kits have been developed for sealing leaks in chlorine containers, drums, and tank cars [263].

Euro Chlor offers a Chlorine Safety Manual [264], recommendations for emergency intervention [265], and for safe design, construction, operation of equipment [266].

Emergency plans have been established for accidents during transportation and use, e.g., CHLOREP [267] in North America and TUIS (Transport Unfall Informations System) in Germany.

13. Quality Specifications and Analytical Methods

13.1. Quality Specifications

Liquid chlorine of commercial quality must have a purity of at least 99.5 wt % [268]. The water content is < 0.005 wt %, and solid residues are < 0.02 wt %. The impurities are mainly CO_2 (≤ 0.5 wt %), N_2, and O_2 (each 0.1 – 0.2 wt %). There are traces of chlorinated hydrocarbons (originating from rubberized or plastic piping) and inorganic salts such as ferric chloride. The chlorine may also contain small amounts of bromine or iodine, depending on the purity of the salt used in the electrolytic process.

13.2. Analytical Methods

Industrial liquid chlorine is mainly analyzed by the methods in ISO regulations. The liquid chlorine is evaporated at 20 °C, and this gas is then analyzed.

Sampling	ISO 1552 [269, 270]
Moisture	ISO 2121 [271], ASTM E410 [272] ISO 2202 [273]
Chlorine content	ISO 2120 [274], ASTM E412 [275]
Gaseous components	DIN 38 408, part 4 [276]
NCl_3	[277]
Mercury	[278], ASTM E506 [279]

The residue is weighed, and the organic constituents are taken up in acetone, hexane, or diethyl ether and determined by gas chromatography. The inorganic residue is analyzed. For quick analysis, liquid chlorine can be introduced directly onto a silica gel column of a gas chromatograph.

Chlorine Gas. The chlorine gas can be analyzed for chlorine content, gaseous impurities, hydrogen, organics, and moisture:

1) Chlorine content. One method for process monitoring and control of chlorine concentration is measurement of thermal conductivity.
2) Gaseous impurities. A known amount of chlorine gas is passed through a solution of potassium iodide or phenol to absorb the chlorine. The residual gases (O_2, N_2, H_2, CO, CO_2) are collected in a gas burette, measured, and analyzed by gas chromatography or with an Orsat apparatus.
3) Hydrogen. A known amount of air is added to the residual gas after removal of the chlorine to ensure excess oxygen, and the volume reduction is measured after the hydrogen is consumed on a heated platinum coil. The hydrogen content can be continuously monitored by thermal conductivity measurement.
4) Organics. Organic components can be determined most conveniently by gas chromatography.
5) Moisture. A known amount of chlorine gas is passed through a drying tube filled with a weighed amount of phosphorus pentoxide. The moisture content is determined from the weight gain of the drying tube (ISO 2121). Continuous determination can be carried out, e.g., by absorption with phosphorus pentoxide and measuring the current required to electrolyze the absorbed water or by the electrical conductivity after absorption in sulfuric acid.

Detection of Chlorine. Chlorine can be recognized by smell or color. Small amounts can be detected by the blue coloration of starch–iodide paper, although other oxidizing agents can produce the same effect. Another method for chlorine detection depends on its ability to combine with mercury. If the unknown gas mixture is shaken with water and mercury, all the chlorine disappears and the remaining water has a neutral reaction. However, if the chlorine contains some hydrogen chloride, the water becomes acidic and reacts with silver nitrate solution to give a white precipitate (AgCl) that is soluble in aqueous ammonia. Leaks in pipes or equipment are detected by testing with the vapor from aqueous ammonia: a thick white cloud of chloride forms.

Quantitative Determination of Free Chlorine. The gas mixture can be shaken with a *potassium iodide solution,* and the liberated iodine can be then determined by titration. Chlorine in alkaline solution can be reduced to chloride by potassium or sodium *arsenite,* and the arsenite can be then oxidized to arsenate. The end point is detected by spot tests with starch–iodide paper. Excess arsenite is back-titrated with acidified potassium bromate solution. Small amounts of chlorine, e.g., in drinking water, can be determined by *photometric measurement* of the yellow color produced by the reaction with *o*-tolidine in hydrochloric acid solution [280].

To determine both *chlorine and carbon dioxide,* the chlorine is absorbed by a solution that contains known amounts of acid and potassium arsenite, and the chlorine is determined by back-titration of the arsenite. The carbon dioxide, which is not absorbed by this solution, is then absorbed by potassium hydroxide solution.

Detection Tubes. Commercial detection tubes (Drägerwerk, Lübeck; Auergesellschaft, Berlin) are available for measuring chlorine in air. They have various ranges: 0.2–3, 2–30, and 50–500 ppm. The Chlorometer (Zeiss-Ikon, Berlin) can determine the free chlorine content of water in a few minutes.

For the protection of the environment and control of working conditions, traces of chlorine as small as 0.01–10 ppm must be determined. There are many types of apparatus on the market for measuring workplace concentrations or emissions. They depend on physicochemical methods, such as conductometry, galvanometry, potentiometry, colorimetry, and UV spectroscopy [281].

14. Uses

The first industrial use of chlorine was to produce bleaching agents for textiles and paper and for cleaning and disinfecting. These were liquid bleaches (solutions of sodium, potassium, or calcium hypochlorite) or bleaching powder (chlorinated lime). Chlorine was then regarded merely as a useful chemical agent.

Since 1900s, chlorine has achieved constantly increasing importance as a raw material for synthetic organic chemistry. Chlorine is an essential component of a multitude of end products, which are used as materials of construction, solvents, pesticides, etc. In addition, it is contained in intermediates that are used to make chlorine-free end products. It is these areas of use that allow chlorine production to increase. The direct use of elemental chlorine, e.g., for sterilizing water, has declined in some areas, but not in others. For example, in Germany, it is $< 0.1\,\%$, but in the United States it is $6\,\%$ (1982). The WHO recommends chlorine as the most useful agent for water disinfection [282].

The percentage of world chlorine consumption of various product groups in 1997 was as follows [283]:

Vinyl chloride	33
Misc. organic products	6
Solvents	19
Pulp and paper	5
Water treatment	6
Others (inorganic products, etc)	31

The number of possible reactions of chlorine, and therefore the number of intermediates and end products, is remarkably large. Some important reactions are shown in Figure 73 along with the areas of application of the end products [284]. Figure 74 also shows some of the applications of chlorine. About one-third of the finished products are chlorine-free, although made with the help of chlorine [285].

Inorganic Products. The use of chlorine to produce pure hydrochloric acid, bleaching agents, and other inorganic products is increasing, although slowly enough that this forms a

Figure 73. Important reactions of chlorine and the uses of the end products

steadily decreasing proportion of the total consumption. The production of some metal chlorides is increasing, e.g., titanium tetrachloride, aluminum chloride, and silicon tetrachloride.

Bleaching. Countries with large paper and cellulose industries had a large chlorine consumption for bleaching purposes. Ecological concerns about AOX (absorbable organic halogens) in the effluents of papermills have led to replacement of elemental chlorine by other bleaching agents, including ozone, hydrogen peroxide, and chlorine dioxide. As a consequence, the use of chlorine is dropping sharply; e.g., United States: 13 % in 1983, 9 % in 1994, 6 % in 2000, 0 % in 2010 (forecast); the decline in Canada and in Scandinavia is even sharper (1983: 60 – 70 %; 1998: near 0 %) [286].

Organic Products. Organic intermediates and end products accounted for up to 85 % of the chlorine use in developed countries. The product with the largest chlorine requirement is *vinyl chloride*, which accounted for 33 % of world chlorine consumption in 1997. This proportion will increase further and outweigh consumption losses in other areas and is therefore the reason for increasing chlorine capacities worldwide.

Figure 74. The chlorine tree (courtesy of Euro Chlor)

Chlorine reacts with methane to give the solvents methyl chloride, methylene chloride, chloroform, and carbon tetrachloride. Butane and pentane are the starting materials for hexachlorobutadiene and hexachloropentadiene, the basis of many pesticides. Chlorinated paraffins are starting materials for detergent raw materials, plasticizers, and lubrication additives.

The chlorination of ethylene first gives 1,2-dichloroethane, which is an important starting material for a variety of further products, including vinyl chloride, ethylene oxide, ethylene glycol, ethylenediamine, and chloral. Other products of the chlorination of ethylene are trichloroethylene, perchloroethylene, etc.

The following products are obtained from propylene: propylene oxide, propylene glycol, carbon tetrachloride (via propylene dichloride), glycerine (via allyl chloride), and epoxy resins and synthetic rubber (via epichlorhydrin).

Aromatic derivatives are also important. The reaction of chlorine with benzene produces the following compounds, among others: monochlorobenzene, dichlorobenzene, and hexachlorobenzene, which are used as solvents or pesticides. A more important use of monochlorobenzene, however, is as an intermediate in the manufacture of aniline, and dyes. A further important synthesis route is to start from toluene to produce toluenediamine and with the

help of phosgene to convert this to toluene diisocyanate, which is used in plastics.

Environmental Aspects. The production and use of chlorine, as well as certain chlorinated substances bear risks for human health and the environment. International discussions are underway on legally-binding conventions and protocols thereof. Matters of concern include the use of mercury, asbestos, chlorine containing materials which are persistant, toxic, and liable to bioaccumulate (e.g., polychlorinated biphenyls, dioxins and furans, DDT, endrine, chlordane), and chemicals having an ozone-depletion potential (e.g., chlorofluorocarbons). Regarding the principles of "Responsible Care" and of "Sustainable Development" [287] the chemical industry is managing this challenge: Once a hazard is realised, the substance in question is handled individually by investigating its properties and its impact on the environment on a scientific basis. Risk assessments and risk – benefit studies are prepared, the results are published as fact sheets, position papers, scientific publications and contributions to the discussion with governments, authorities, and the public. Practical measures for reducing the risks are continuous efforts to reduce or eliminate emissions (mercury, asbestos), offer recycling concepts for products (PVC, chlorinated solvents), improve production processes and transportation safety, cease the production (CFCs, pentachlorophenol in most countries) or marketing of problematic compoundes, and developing for alternative processes (bleaching in the pulp and paper industry). All these measures are influencing the use pattern of chlorine: the use for bleaching, for C_1 compounds, for solvents, and for tetraethyllead will further decrease; the importance of organic chemicals will rise and PVC will expand especially in the construction sector. A study conducted by ECOTEC [288] illustrates the chlorine flow within the industrial production system and to external consumers.

15. Economic Aspects

In Western Europe in 1995 [289]:

- Almost 2×10^6 jobs were related to chlorine
- 55 % of European chemical turnover depended on chlorine
- 85 % of pharmaceuticals are made using chlorine
- 98 % of Western Europe's drinking water is purified by chlorination

These figures demonstrate the economic importance of the chlorine industry.

Figure 75 shows how world chlorine production has developed from 1965 to 1995. The figures are only estimates, as many important nations do not publish this information.

Figure 75. World chlorine production (1965 – 1995)

Chlorine capacities 1995 (in 10^3 t/a) in the main producer countries was as follows [290]:

United States	11 860
Japan	4250
Former Soviet Union	3800
China	3750
Germany	3690
Brazil	1660
Canada	1630
France	1580
United Kingdom	1270
India	1230
Italy	1130

World chlorine capacity was about 40×10^6 t/a in 1983, it rose to 48×10^6 t/a in 1998, and is forecast to reach 55×10^6 t/a by 2005 [283].

Figure 76 demonstrates the growth of chlorine capacity by economic regions [291]. Compared to 1983, the capacities in 1997 remained nearly constant in Western Europe, Eastern Europe, and Africa. In North America, reductions

Figure 76. Chlorine production capacities by economic regions (1983 and 1997)

in Canada were outweighed by growth in the United States. Huge capacities were erected in the Middle East and above all in Asia and Oceania (China, India), where capacities were tripled. From the growth between 1997 and 2005, North America's share will be 35 %, Asia's 40 %, and the Middle East's 15 % [283]. After 2000 China will become the second biggest producer after the United States, with an annual chlorine capacity of about 5.5×10^6 t.

All chlorine producers are listed in [292]. A detailed review of the chlor-alkali market for 1994 is given in [293].

The production costs of 1 electrochemical unit ($\triangleq$ 1 t chlorine + 1.13 t sodium hydroxide) depends up to 60 % on the price of electricity. At 3.5 *d*/kWh, they are about 250 \$/ecu (Fig. 77), so the total value of production is ca 24×10^9 \$/a. The chlor-alkali industry is one of the biggest consumers of electrical energy, consuming ca. 0.15×10^{12} kWh/a.

A prediction of the market prices for chlorine and for caustic soda is very difficult. Firstly, most chlorine is used captively to avoid transportation, or it is sold on the basis of long-term contracts. In relation to production, the amounts on the spot markets are small. Secondly, the production of chlorine is strictly coupled to that of the caustic soda. A strong demand for chlorine creates a surplus of caustic, leading to high prices for the chlorine and a drop in prices for caustic; weak demand for chlorine reduces the available amount of caustic, leading to high caustic prices and low chlorine prices. This situation seems to change in cycles every 6 to 8 years. For example, from 1988 to 1991 the market value for chlorine fell from 150 \$/t down to 0, but from March 1992 to August 1993, the price rose to 230 \$/t. The price for caustic was 320 \$/t in 1991; it fell to 50 \$/t in March 1994 and climbed to 270 \$/t in December 1994 (Fig. 77) [294].

Because of the fixed ratio of chlorine to caustic in production and the different location of uses, worldwide trade flows have been created for both products. Chlorine is traded as chlorinated derivatives, particularly as EDC, VCM, and PVC, accounting for 85 %, and chlorinated solvents. The equivalent annual amount of chlorine is approximately 4.5×10^6 t (1995 to 2000). The main exporting countries are the United States (to South East Asia, South America), Russia (to West Europe), West Europe (to South East Asia, China), Japan (to China), and Middle East Asia (to Japan , China). [295].

16. Toxicology

Chlorine gas is dangerous to health because it is a powerful oxidant. In the physiological pH range, it is converted to hypochlorous acid, a cytotoxic substance. The extent to which the cells are damaged depends on the gas concentration, the exposure time, the water content of the tis-

Figure 77. Production costs and product prices in the United states from 1987 to 1997 [294]
a) Product value for 1 ecu (1 t Cl_2 + 1.13 t NaOH; b) Price for caustic soda; c) Production costs for 1 ecu at 3.5 ¢/kWh electricity price; d) Price for chlorine into PVC

sue, and the health of the person exposed to the gas. Besides getting into the eyes, larynx, and trachea, chlorine also reaches the bronchi and the bronchioles. Because of its moderate solubility in water, chlorine affects the alveoli only at high concentrations. In this respect, chlorine differs from other gases with low water solubility and high lipid solubility, such as phosgene, nitrogen monoxide, and nitrogen dioxide. Initial moderate bronchial irritation is followed by the development of a toxic pulmonary edema because of increased alveolar injury.

The olfactory threshold of chlorine gas is 0.2 – 3.5 mL/m^3. Prolonged exposure seems to raise the olfactory threshold. Concentrations of 3 – 5 mL/m^3 are tolerated for up to 30 min without any subjective feeling of malaise. At concentrations between 5 and 8 mL/m^3, mild irritation of the upper respiratory tract and the conjunctiva is observed. In addition, running of the eyes and coughing are observed at concentrations of 15 mL/m^3 and higher. Above 30 mL/m^3, the following symptoms are observed: nausea, vomiting, oppressive feeling, shortness of breath, and fits of coughing, sometimes leading to bronchial spasms. Exposure to 40 – 60 mL/m^3 leads to the development of toxic tracheobronchitis. After a latent period of several hours with fewer symptoms, pulmonary edema may occur because of alveolar membrane destruction. This is indicated by increased shortness of breath, restlessness, and cyanosis. Subsequently, a further complication can occur after several days in the form of pneumonia caused by superinfection of the injured pulmonary tissue.

A clear dose – effect relationship of chlorine gas at different concentrations in humans has not yet been published. On the basis of results obtained from animal experiments, the LC_{50} for healthy humans is assumed to be 300 – 400 mL/m^3 at a 30-min exposure [296]. No deaths have occurred in animal experiments at 30-min exposures for concentrations below 50 mL/m^3. Death following acute intoxication is caused by a fulminant pulmonary edema.

Many investigations deal with the toxicity of *low chlorine concentrations.* Investigations in humans indicate the possibility of reversible damage to the lung function parameters at concentrations starting at 1.0 mL/m^3, whereas 0.5 mL/m^3 is a no-observable-effect-level [297, 298]. In monkeys no effects have been observed

at 0.5 mL/m^3 in a one-year study [299]. Long-term investigations of workers exposed to chlorine, e.g., in chlor-alkali electrolysis plants or in pulp manufacture, however, do not indicate increased rates of mortality or morbidity caused by pulmonary diseases [300 – 303].

No indications of *carcinogenicity* or *mutagenicity* of chlorine have been detected in animal experiments or encountered in industrial medicine [304]. In Germany, the MAK value is 0.5 mL/m^3 (1.5 mg/m^3) with a 15-min excursion factor of 1 [304]; in the USA, the TLV is 0.5 mL/m^3 (1.5 mg/m^3) with a STEL of 1.0 mL/m^3 (3 mg/m^3).

tions. Table 1 shows some important properties of these chlorine oxides. Other chlorine oxides, such as *dichlorine dioxide* [*12292-23-8*], Cl_2O_2, *dichlorine trioxide* [*17496-59-2*], Cl_2O_3, or *dichlorine tetroxide* [*27218-16-2*], Cl_2O_4, are unstable.

The chlorine oxygen acids are formed by reaction of the corresponding chlorine oxides with water.

Hypochlorous acid [*7790-92-3*], HClO:

$$Cl_2O + H_2O \longrightarrow 2\,HClO$$

Chlorous acid [*13898-47-0*], $HClO_2$:

$$2\,ClO_2 + H_2O \longrightarrow HClO_2 + HClO_3$$

Chloric acid [*7790-93-4*], $HClO_3$:

$$Cl_2O_6 + H_2O \longrightarrow HClO_3 + HClO_4$$

Perchloric acid [*7601-90-3*], $HClO_4$:

$$Cl_2O_7 + H_2O \longrightarrow 2\,HClO_4$$

Table 2 lists the thermodynamic properties of chlorine oxides, chlorine oxygen acids, and their sodium salts [1].

The *oxidation power* of individual chlorine oxygen compounds is characterized by the changes in the standard enthalpy ΔH° and Gibbs free energy ΔG° of the decomposition reactions forming molecular oxygen (Table 3). As shown in Table 3, the thermodynamic stability of chlorine oxygen acids and chlorine oxides increases with increasing oxidation state of the chlorine atom. Therefore, concentrated perchloric acid can be isolated, whereas all other oxygen acids are stable only in diluted form. The instability of the chlorine oxides and their acids determines their industrial significance. All chlorine oxygen compounds are strong oxidants; the strongest are those with the lowest oxidation state of the chlorine atom.

Dichlorine oxide, Cl_2O, chlorine dioxide, ClO_2, all oxygen acids, and their salts, particularly those of sodium and potassium, are used industrially.

History. Soon after the discovery of chlorine in 1774, scientific and commercial interest was directed to the chlorine oxides, the chlorine oxygen acids, and their salts.

Hypochlorite was first prepared in 1787 by C. L. Berthollet by feeding chlorine into potash lye. This bleach liquor (eau de Javel) was soon applied in bleaching textiles and in papermaking. Labarraque replaced potash lye by the cheaper soda lye (eau de Labarraque).

Hypochlorite was prepared by electrolysis of sodium chloride as early as 1801. However, commercial electrochemical production did not start for a long time.

At the beginning of the 20th century, the traditional routes to form bleach liquors [2] fell out of use by the rapidly expanding chlorine – caustic industry that made large quantities of cheap waste chlorine available. Within the last 20 years, however, electrosynthesis has found a widespread revival and is today an alternative to chemical hypochlorite production wherever safety risks of small plants are decisive.

In 1799 C. Tennant and C. McIntosh developed a process for the production of *bleaching powder* by absorbing chlorine onto dry calcium hydroxide. This bleaching powder was much more stable than previously obtained bleaching products. In 1906, G. Pistor succeeded in producing highly concentrated bleach-

ing powder with more than 70 % available chlorine.

R. Chevenix first made *chlorine dioxide* in 1802 by the reaction of concentrated sulfuric acid and potassium chlorate, but the product was first identified by H. Davy and F. von Stadion in 1815/1816. Calvert and Davies used oxalic acid instead of sulfuric acid in 1859 and obtained chlorine dioxide together with carbon dioxide, thus eliminating the explosion risk. This and the investigations of E. Schmidt in 1921 – 1923 [3] laid the ground to today's extensive use of chlorine dioxide as a bleaching agent in the textile, pulp, and paper industry.

J. R. Glauber probably prepared *chlorate* for the first time, but C. L. Berthollet first made chlorate in 1787 by the reaction of chlorine with potassium hydroxide and identified it as the salt of chloric acid. The first electrochemical chlorate preparation was performed by W. von Hisinger and J. J. Berzelius in 1802. In 1851 a cell patent was granted to C. Watt that had the essential features of later cells, but industrial production did not start before 1886. Originally, all cells were operated with an alkaline electrolyte until J. Landin added chromic acid to the electrolyte and solved the problem of cathodic hypochlorite reduction [4], [5]. Within the few years before and after 1900, scientific research focused on the mechanism of chlorate formation [6–12]; this was supplemented by numerous investigations within the last 30 years. However, the detailed reaction mechanism is still a subject of scientific debate.

The most important technological improvements were (1) the separation of the electrochemical reactor from the chemical reactor in 1933 (A. Schumann-Leclercq) [13], (2) the utilization of the hydrogen formed at the cathode for "stirring" the electrolyte [14], and (3) the introduction of dimensionally stable titanium anodes 20 years ago [15].

F. von Stadion first made *perchlorates* by oxidation of chlorate at platinum anodes in 1816; he also obtained perchloric acid by the reaction of concentrated sulfuric acid with potassium perchlorate and by anodic oxidation of hydrochloric acid. Preparation of perchloric acid by electrolysis of dilute chloric acid was first carried out by J. J. Berzelius in 1835. Like all other electrochemical production methods, electrosynthesis of perchlorate and perchloric acid did not gain industrial significance before the end of the 19th century. In 1890, O. Carlson was granted a patent for electrochemical perchlorate production, and in 1895 he operated the first commercial plant in Sweden. The first methodic studies of the reaction fundamentals were initiated by German researchers in 1898 [16–18].

General Significance. The importance of chlorine oxygen compounds is based predominantly on their oxidizing power. For 200 years, after the lawn bleaching of textiles became obsolete, the textile and paper industry has invariably been a main consumer of chlorine dioxide and hypochlorite. The importance of these products has steadily grown in accordance with the expansion of the pulp and paper industry. Traditional uses of chlorate as a herbicide or explosive became less important. On the other hand, the increasing demand for disinfection of process and drinking water and for sanitation in general has strongly favored the use of chlorine oxygen compounds. The importance of chlorinated lime as a disinfectant has declined. However, other chlorine oxygen compounds, above all hypochlorite, have grown. This trend was particularly favored by the danger of handling chlorine. Moreover, some of the chlorine oxygen compounds have found numerous novel uses that are reported in detail in the following chapters.

Today, chlorate production is one of the most important inorganic electrosyntheses. In addition, perchlorates are preferably made by electrochemical processes. On the basis of a deeper understanding of the chemical and electrochemical fundamentals and by introducing dimensionally stable anodes, design and operation of electrochemical plants have been revolutionized to such an extent that a modern electrochemical reactor has very little resemblance to a cell 20 years ago.

2. Hypochlorous Acid

Hypochlorous acid [*7790-92-3*], HOCl, M_r 52.5, is only moderately stable in aqueous solution. It is colorless when dilute and yellowish at higher concentrations. Hypochlorous acid is one of the most powerful oxidizing agents known.

Hypochlorous acid solution decomposes exothermically. The main decomposition products are hydrochloric acid and oxygen:

$$2\,HOCl \longrightarrow 2\,HCl + O_2$$

Minor amounts of chlorine and chloric acid are also formed.

Production. Hypochlorous acid is produced by the reversible reaction of chlorine and water:

$$Cl_2 + H_2O \rightleftharpoons HOCl + HCl$$

For efficient conversion, hydrochloric acid must be removed from the equilibrium mixture. This is achieved by limestone, $CaCO_3$, soda ash, Na_2CO_3, or calcium hypochlorite, $Ca(OCl)_2$.

One of the common ways to produce hypochlorous acid is to pass chlorinated water through towers packed with powdered limestone [19]. The overall reaction is as follows:

$$2\,Cl_2 + 2\,H_2O + 2\,CaCO_3 \longrightarrow 2\,HOCl + CaCl_2 + Ca(HCO_3)_2$$

Calcium hydrogen carbonate present in the resulting solution provides the buffer needed to stabilize the product. Any hydrochloric acid still produced is removed by the reaction

$$Ca(HCO_3)_2 + 2\,HCl \longrightarrow CaCl_2 + 2\,H_2O + 2\,CO_2$$

Hypochlorous acid can also be prepared by passing a mixture of dry chlorine and air through a column packed with yellow mercuric oxide, HgO. The resulting dichlorine oxide is dissolved in water to produce hypochlorous acid [20], [21].

Storage. Because of its limited stability, hypochlorous acid is best used soon after production. Its long-distance transport or intermediate storage should be avoided.

A solution containing less than 1 % hypochlorous acid can be stored in the dark over fairly long periods, provided that such metals as copper, nickel, or cobalt are absent. Solutions containing 30 % hypochlorous acid can also be stored, but at temperatures of −20 °C or lower.

Uses. Because of its instability, hypochlorous acid is not used extensively as an oxidizing or bleaching agent. It was used mainly in the water treatment industry for slime control, for treatment of drinking water, and for sterilization of swimming pools. These applications have now been taken over by the more stable hypochlorites.

3. Solid Hypochlorites

3.1. Properties

All solid hypochlorites are soft, white, dry powders. Some are almost odorless; others smell more or less strongly of chlorine or hydrochloric acid because of decomposition during storage (Eqs. 1 – 3). The stability of hypochlorites depends primarily on their water content, which is usually less than 1 %; tropical bleach contains even less than 0.3 %. They are stable up to 80 °C, tropical bleach even up to 100 °C. When heated to 180 °C, they decompose into chloride and oxygen. Such metals as iron, nickel, or cobalt decrease the stability of hypochlorites. Therefore, the raw materials used for the production of hypochlorites must be free of such metals. *Tropical bleach* (< 0.3 % water) free of heavy metals has a shelf life of more than 2 years, if properly stored.

If not properly stored in air-tight containers, hypochlorites suffer loss of available chlorine because of reaction with water:

$$Ca(OCl)_2 + CaCl_2 + 2\,H_2O \longrightarrow 2\,Ca(OH)_2 + 2\,Cl_2 \qquad (1)$$

or reaction with carbon dioxide:

$$Ca(OCl)_2 + CaCl_2 + 2\,CO_2 \longrightarrow 2\,CaCO_3 + 2\,Cl_2 \qquad (2)$$

or reaction with both:

$$Ca(OCl)_2 + CO_2 + H_2O \longrightarrow CaCO_3 + 2\,HOCl \qquad (3)$$

3.2. Production

Bleaching Powder. Standard bleaching powder is a mixture of calcium hypochlorite [*7778-54-3*], $Ca(OCl)_2$, calcium chloride, and calcium hydroxide containing varying amounts of water. It is made by passing chlorine over hydrated lime. The Rheinfelden bleaching powder process of Dynamit Nobel is a batch operation [22]. Dry, powdered lime hydrate is chlorinated at 45 °C and low pressure (5.3 kPa) in a horizontal reaction drum. Chlorine is injected as a liquid. The reaction mass is permanently mixed by a slowly rotating rake. The reaction of solid lime hydrate and chlorine leads to the formation of a mixture of dibasic calcium hypochlorite [*12394-14-8*], $Ca(OCl)_2 \cdot 2\,Ca(OH)_2$, and basic calcium chloride, corresponding to 40 % conversion of the available calcium hydroxide. The following equation characterizes the reaction [23], [24]:

$$5\,Ca(OH)_2 + 2\,Cl_2 \longrightarrow Ca(OCl)_2 \cdot 2\,Ca(OH)_2 + CaCl_2 \cdot Ca(OH)_2 \cdot H_2O + H_2O$$

On further chlorination, hemibasic calcium hypochlorite [*62974-42-9*], $Ca(OCl)_2 \cdot 1/2\,Ca(OH)_2$, and neutral calcium chloride hydrate are formed. After ca. 60 % of the available calcium hydroxide has been converted, the bleaching powder reaction stops; this can be represented by the following equation:

$$10\,Ca(OH)_2 + 6\,Cl_2 \longrightarrow Ca(OCl)_2 \cdot 2\,Ca(OH)_2 + 2\,Ca(OCl)_2 \cdot 1/2\,Ca(OH)_2 + CaCl_2 \cdot Ca(OH)_2 \cdot H_2O + 2\,CaCl_2 \cdot H_2O + 3\,H_2O$$

The reaction is strongly exothermic, generating 1100 kJ of heat per kg of chlorine converted. This heat and the low pressure cause the water formed during the reaction and the liquid chlorine to evaporate. Consequently, the reaction mass is dried completely under vacuum at a maximum temperature of 85 °C. The product is standard bleaching powder of 35 – 37 % available chlorine content (for definition, see Section 3.3).

Gaseous chlorine can also be used for this reaction, but then the reaction takes 2 – 3 times longer, chlorine losses are higher, and the available chlorine content of the product is smaller.

Tropical Bleach. To reduce the water content further, finest ground quicklime, CaO, is added to the bleaching powder. It absorbs any water still present and is converted into calcium hydroxide. Although this operation decreases the

available chlorine content by 1 – 2 %, the extra drying makes the resulting bleaching powder, known as tropical bleach, stable up to temperatures of 100 °C.

ICI has developed a continuous process for the production of bleaching powder, in which countercurrents of calcium hydroxide and chlorine react in a rotating drum [25]. The heat of reaction is removed by spraying the drum externally with water and by diluting the chlorine with cooled air; this gas stream also removes the water formed during the chemical reaction.

High-Percentage Hypochlorite. Solid hypochlorites with 70 % and higher available chlorine contents can be prepared by chlorinating slurries of such calcium compounds as calcium hydroxide, or bleaching powder. Initially, hemibasic calcium hypochlorite, $Ca(OCl)_2 \cdot 1/2\,Ca(OH)_2$, is formed. When further chlorinated, this gives neutral calcium hypochlorite dihydrate, $Ca(OCl)_2 \cdot 2\,H_2O$, which is then dried to the desired high-percentage hypochlorite. In all of these reactions, calcium chloride is formed as a byproduct [26–28]. Some processes recover the calcium values by adding sodium hypochlorite to the slurries:

$$2\,NaOCl + CaCl_2 \longrightarrow Ca(OCl)_2 + 2\,NaCl$$

In such cases, the product primarily consists of calcium hypochlorite, sodium chloride, and water, which is then removed [29].

Barium and Magnesium Hypochlorite. Barium hypochlorite [*13477-10-6*], $Ba(OCl)_2$, can be produced in large crystals with a maximum available chlorine content of 59 %. It is more stable than calcium hypochlorite but also more expensive because of the high cost of raw materials.

Magnesium hypochlorite [*10233-03-1*], $Mg(OCl)_2$, is extremely unstable and decomposes when dried.

3.3. Quality Specifications

The term *available chlorine content*, also called *active chlorine*, represents the mass fraction of liberated chlorine in bleaching powder when bleaching powder reacts with hydrochloric acid.

The following qualities of solid hypochlorites are available (content of available chlorine, wt %, in parentheses): tropical bleach (34 – 35), bleaching powder (35 – 37), and high-percentage hypochlorite (70).

3.4. Uses (→ Bleaching)

In the paper industry, calcium hypochlorite is used in single-stage bleaching. The more expensive sodium hypochlorite is used in the multistage process, which involves chlorination, caustic extraction, and hypochlorite oxidation. Kraft pulp is processed to higher brightness and greater strength when sodium hypochlorite is used instead of calcium hypochlorite.

For bleaching in laundry operations, bleaching powder is first suspended in water and then decanted. Only the solution is used because the insolubles could damage the fibers.

4. Hypochlorite Solutions

The reaction of gaseous chlorine with a slight excess of alkali produces highly concentrated hypochlorite solutions. Available chlorine concentrations of 170 – 220 g/L can be obtained, or even more if the residual chloride concentration is lowered extremely [30]. Hypochlorite solutions are relatively safe and are often chosen instead of chlorine for bleaching, disinfection, biofouling control, and odor control. Concern regarding the safety hazards associated with liquid chlorine has grown. Several major cities now restrict transportation of chlorine within their boundaries, and a great deal of attention has focused on accidents caused by the handling of liquid chlorine by unskilled labor [31]. This has increased the popularity of hypochlorite solutions in spite of their relatively high cost.

An attractive alternative to the chemical production of hypochlorite solutions described above is the on-site electrolysis of brine or seawater. Such processes are described in Section 4.2.

Stability. Hypochlorite solutions are more stable than solutions of hypochlorous acid, but they are active enough to be used as disinfectants or bleaching agents. The factors that affect the

stability of the parent acid also affect the stability of hypochlorite solutions: concentration, presence of such metals as copper, nickel, or cobalt, pH, temperature, and exposure to light.

Available Chlorine. When chlorine reacts with caustic soda, half of the chlorine is lost because inert sodium chloride is formed:

$$Cl_2 + 2\,NaOH \longrightarrow NaOCl + NaCl + H_2O$$

However, as an oxidant, sodium hypochlorite decomposes to sodium chloride and oxygen:

$$NaOCl \longrightarrow NaCl + [O]$$

The oxidizing power of one oxygen atom is equivalent to that of two chlorine atoms. Therefore, the complete oxidizing power of the original chlorine is available in the hypochlorite solution; it is expressed in grams of available chlorine per liter of finished solution. Thus, the "available chlorine" of hypochlorite solutions compares the oxidizing power of the agent to that of the equivalent amount of elemental chlorine used to make the solution.

4.1. Chemical Production

A hypochlorite unit is attached to each chlor-alkali plant to render harmless the dilute chlorine that cannot be recovered economically. These units make most of the industrially produced hypochlorite solutions [32–34].

Beyond that, hypochlorite solutions with available chlorine contents higher than 5 g/L are made by passing chlorine gas through dilute solutions of sodium hydroxide or potassium hydroxide. Calcium hydroxide suspensions may also be used, from which, after filtration or decantation, clear calcium hypochlorite solutions are obtained [35].

4.1.1. From Chlorine

In the commercial production of hypochlorite solutions from chlorine gas and alkali solutions of various concentrations, the following conditions must be maintained.

1) The temperature must be controlled at 30 – 35 °C.
2) The solution must be alkaline at any stage.
3) The equipment must provide for thorough mixing and escape of inert gas.
4) Such heavy metals as manganese, iron, cobalt, nickel, or copper must be avoided in the system.
5) Available chlorine contents of more than 150 g/L should be avoided. The high decomposition rate of such concentrated solutions more than offsets any savings in transportation [36].

Sodium or Potassium Hypochlorites. Figure 1 shows a schematic diagram of a typical process for the commercial production of hypochlorite solutions. The continuous process can produce hypochlorite solutions of any available chlorine content between 0 and 150 g/L and any amount between zero and the designated capacity. The only parameters to be adjusted are the redox potential of the analyzer (b) and the desired dilutionof the caustic soda solution. For a given amount of chlorine coming in, the system automatically adjusts the caustic soda, process water, and hypochlorite solution flows into and out of the system.

Chlorine gas, diluted with air, is introduced into the chlorination column (a), packed with Raschig rings. Caustic soda is diluted to the desired concentration with water. Tank (d) provides for buffer capacity and homogenization. The pumps (e) circulate the mixture of caustic soda and sodium hypochlorite through the titanium heat exchanger (f), the chlorination column (a), and the tank (d).

Any amount of chlorine between zero and the designated capacity is absorbed in the circulating caustic, producing sodium hypochlorite. When the available chlorine concentration reaches the desired value, the analyzer (b) signals to open control valve (c) for the withdrawal of sodium hypochlorite to the storage tank (g). In this case, the liquid in tank (d) must be replenished by fresh caustic.

The storage tank (g) is equipped with a circulation pump and a heat exchanger to keep the temperature of the stored hypochlorite solution below 35 °C. If necessary, the inert gas leaving column (a) can be scrubbed before entering the atmosphere.

Figure 1. Production of hypochlorite solution from chlorine and caustic soda
a) Chlorination column; b) Analyzer; c) Control valve; d) Buffer tank; e) Pumps; f) Heat exchangers; g) Storage tank

Materials of Construction. All pumps have rubber-lined steel casings and titanium propellers. The heat exchangers are plated with titanium. The tanks (d) and (g) are made from fiberglass-reinforced plastic [37]. The same material is used for the chlorination column and the pipes; chlorinated poly(vinyl chloride) is an alternative material for the pipes.

Calcium Hypochlorite. If a solution of calcium hypochlorite is desired, milk of lime – a suspension of calcium hydroxide in water – is chlorinated. (The solubility of calcium hydroxide in water is 1.3 g/L at 20 °C.) In that case, the plant described in Figure 1 must be modified to handle the solid phase.

In addition to design changes in the equipment, no packing is needed in the chlorination column and the piping must be designed to ensure that pockets are avoided where solid particles can settle and block the pipes; a settler or filter is needed to remove all insoluble or suspended particles before a clear solution of calcium hypochlorite flows to the storage tank.

4.1.2. From Bleaching Powder

To avoid long-term storage of hypochlorite solutions, laundries prefer to store solid bleaching powder and then prepare the sodium hypochlorite solutions by using sodium carbonate, sodium sulfate, or caustic soda:

$$CaCl(OCl) + Na_2CO_3 \longrightarrow NaOCl + NaCl + CaCO_3$$

$$CaCl(OCl) + Na_2SO_4 \longrightarrow NaOCl + NaCl + CaSO_4$$

$$CaCl(OCl) + 2\,NaOH \longrightarrow NaOCl + NaCl + Ca(OH)_2$$

A disadvantage of this method is the precipitation of $CaCO_3$, $CaSO_4$, or $Ca(OH)_2$, which requires filtering or settling before the hypochlorite solution can be used.

4.2. Electrosynthesis

On-site, electrochemical production of dilute hypochlorite solution has long been recognized as an option wherever long-term storage of hypochlorite is unnecessary; it is now rapidly gaining popularity [38]. Hypochlorite solutions with an available chlorine content of up to 10 g/L are commonly produced on the site in electrochemical cells by using either prepared brine or natural seawater as feed.

4.2.1. Reaction Fundamentals

Electrolysis of sodium chloride yields chlorine at the anode:

$$2\,Cl^- \longrightarrow Cl_2 + 2\,e$$

The final product depends on the operational conditions of the cell. In the production of chlorine gas, special care is taken to prevent mixing of anode and cathode products (→ Chlorine). Chlorine hydrolyzes and hypochlorous acid dissociates, forming hypochlorite and chloride in solution [39], [40]:

$$Cl_2 + H_2O \rightleftharpoons HClO + Cl^- + H^+$$

$$HClO \rightleftharpoons ClO^- + H^+$$

The formation of hypochlorous acid and hypochlorite ceases when the electrolyte is saturated with chlorine and chlorine gas evolves at pH 2–3.

However, in the electrosynthesis of hypochlorite, as well as of chlorate, anolyte and catholyte are vigorously mixed. The hydroxyl ions formed at the cathode

$$2\,H_2O + 2\,e \longrightarrow 2\,OH^- + H_2$$

maintain the electrolyte near neutrality (pH 7–9). Under this condition, the concentration of dissolved chlorine near the anode surface remains too low to permit evolution of gaseous chlorine, and hypochlorite is the main product.

There are four main loss reactions that complicate industrial operation; they have been studied to optimize the operating conditions [41], [42] and are described in the following paragraphs in more detail.

Cathodic Reduction. Hypochlorite is reduced at the cathode to form chloride:

$$ClO^- + H_2O + 2\,e \longrightarrow Cl^- + 2\,OH^-$$

The rate of this reaction is controlled by mass transfer and is, thus, linearly proportional to the overall hypochlorite concentration; it increases with flow rate and temperature [42–45].

Loss by cathodic reduction also occurs in chlorate production; in that case it is minimized by adding dichromate to the electrolyte (see Section 7.2.2). This remedy is not possible in the simple flow-through hypochlorite cells, and loss in commercial cells is considerable, as Figure 2 shows.

Several means are used to lower reduction loss. Smooth cathode surfaces are superior to rough surfaces [45]. Loss is also lowered by decreasing the active area of the cathodes, thereby increasing the cathode current density. Cathodic reduction was greatly suppressed by decreasing the active area to ca. 1 % with a synthetic resin coating [42]; however, the attendant voltage increase makes this approach industrially unattractive. Bubbles always cover a portion of the cathode surface and contribute to lower cathodic reduction. Hydrogen evolution increases cathodic reduction because its stirring action enhances the mass transfer coefficient. Efforts to lower the mass transfer coefficient by covering the cathode with a porous plastic have also been successful at suppressing cathodic reduction [47]. Similarly, the inhibitory action of calcium chloride was related to the formation of insoluble compounds on the cathode surface [48].

Anodic Oxidation. Anodic oxidation of hypochlorite to chlorate is used in industry and is described in detail in Section 7.3:

$$3\,ClO^- + 1.5\,H_2O \longrightarrow ClO_3^- + 3\,H^+ + 2\,Cl^- + 0.75\,O_2 + 3\,e$$

This reaction is also controlled by mass transfer, and its rate increases with the hypochlorite concentration. Because hypochlorite is decomposed at the anode and cathode, commercial on-site production is restricted to a maximum concentration of available chlorine of ca. 10 g/L; this is usually sufficient for disinfecting and deodorizing water. The contribution of anodic oxidation to the overall loss can further be lowered by increasing the anodic current density; however, the anode lifetime may then decrease. The loss reaction may also depend on the anode material: dimensionally stable anodes based on RuO_2 were found to be more efficient than platinized titanium or graphite [42].

Anodic Water Electrolysis. This loss reaction competes with chlorine discharge, and its rate depends on the chloride concentration, various mass transfer coefficients, and the nature of the anode material.

$$H_2O \longrightarrow 1/2\,O_2 + 2\,H^+ + 2\,e$$

When NaCl concentrations are greater than 100 g/L, the loss is small. However, a typical NaCl concentration in a modern brine cell is ca.

Figure 2. Current efficiency loss vs. available chlorine concentration (NaCl: 28 g/L, 25 °C, 1550 A/m^2) [46]

30 g/L, at which the rate of water decomposition is significant, as shown in Figure 2.

When salt must be purchased, the conversion of chloride into hypochlorite must be maximized. A typical on-site electrosynthesis from prepared brine consumes 3 – 5 kg of salt per kg of available chlorine produced. The question of chloride consumption is meaningless where natural seawater is used as a feed. However, in cases of low salinity or very cold seawater, oxygen evolution caused by anodic water electrolysis may decrease current efficiency by as much as 40 % [49].

As in the case of chlorate synthesis, the nature of the anode material strongly influences the amount of water decomposition. Platinized titanium and dimensionally stable anodes based on RuO_2 are more selective for chlorine evolution, whereas PbO_2 and graphite anodes have a greater tendency to evolve oxygen.

Chemical Chlorate Formation. Autoxidation of hypochlorite to chlorate is the preferred route of commercial chlorate production (Section 7.3). The rate of this reaction depends on pH and temperature; in industrial hypochlorite production, it is minimized by keeping the temperature below 40 °C and the pH above 7 [41].

4.2.2. Industrial Cells

The number of companies offering hypochlorite cells has grown quickly in the past few years. Over 20 suppliers offer a wide variety of cell designs. They can all be classified into three basic types: (1) tube cells, (2) parallel-plate cells, and (3) rotating or mechanical scraper-type cells. Of the modern hypochlorite cells, the tube cells were developed first. They generally consist of two concentric pipes, one being the anode and the other the cathode, with the annular space serving as the electrode gap. This type of cell may be operated under pressure and is well-suited for small applications. Parallel-plate cells achieve a much better packing of electrode area, and most large industrial installations use cells of this type. Only two of the manufacturers offer rotating or mechanical scraper-type cells. In theory, such cells should be able to operate indefinitely without deposit buildup, and would therefore result in low maintenance cost. In practice, however, their extra mechanical action is difficult to maintain, and such cells have not yet captured a significant market share.

Seawater Cells. Cells designed to operate by using natural seawater are different from those using prepared brince. Cells using seawater tend to operate at a higher electrolyte flow rate and a wider electrode gap than brine cells to minimize problems arising from cathode deposits. Seawater cells also produce a lower product con-

centration, typically solutions with an available chlorine content of 0.5 – 4.0 g/L. Hypochlorite concentration is kept low to maximize current efficiency whenever high salt usage is not a concern (see also Table 4).

Table 4. Typical operational data of electrolytic cells for hypochlorite generation

Parameter	Brine feed	Seawater feed
Current density, A/m^2	1500	1500
Current efficiency, %	65	90
Temperature, °C	25	5 – 25
Concentration		
NaCl (cell entrance), g/L	30	15 – 30
Available chlorine (cell exit), g/L	8 – 10	1.0 – 3.0
Energy consumption, kW/h/kg of available chlorine	4.5 – 5.0	3.3 – 4.1
Sodium chloride consumption, kg of NaCl per kg of available chlorine	3 – 3.5	

Figure 3. Typical layout for a brine hypochlorite cell system
a) Automatic brine makeup; b) Brine storage tank; c) Water softener; d) Rectifier; e) Hypochlorite cell; f) Hypochlorite storage tank

Brine Cells. Brine cells usually produce solutions with an available chlorine content of 7 – 10 g/L to keep salt cost low. Most manufacturers offer brine cells of the same design as their seawater cells, but electrolyte flow rate is lowered to maximize current efficiency at the higher concentration of available chlorine. Figure 3 shows a flow diagram for a typical system designed for electrolysis using prepared brine. Although brine cells were developed first, they now have only a small share of the total on-site hypochlorite cell market.

Table 4 shows typical operational data of seawater and brine feed cells.

Figure 4. Sanilec seawater electrolysis cell

Sanilec System. Eltech System Corp. first offered the Sanilec system for seawater electrolysis in 1973. The cells are of a parallel-plate design (Fig. 4) and feature once-through operation without recycle [31]. Cells producing 30, 70, 140, or 155 kg/d can be banked in series to produce hypochlorite solutions of available chlorine concentrations up to 3.0 g/L. Full-load a.c. power consumption is as low as 4.1 kWh per kg of chlorine, partly because dimensionally stable anodes are used. These cells use cathodes made of nickel alloys and remove hydrogen pe-

riodically to lower power consumption. Typical operational data are shown in Table 4.

Chloropac System. Englehard Minerals & Chemical Corp. produces tube cells with concentric titanium pipes as anode and cathode under the trade name of Chloropac System [50]. These cells are designed for an operating pressure of 1000 kPa. They utilize a high seawater flow rate to minimize deposit formation.

As shown in Figure 5, the electrodes are assembled in a bipolar arrangement, which is particularly suited for smaller capacities. The platinized titanium anodes are coated with 5 µm of platinum and have good current efficiency for chlorine evolution. The power consumption is claimed to be 3.5 – 5.0 kW h per kg of chlorine.

M. G. P. S. System. Mitsubishi Heavy Industries offers monopolar plate-type cells arranged in series under the name of the M. G. P. S. system. The cell body is made from mild steel lined with rubber, and the system is well-suited for large industrial applications. Cathodes are made from titanium and anodes from platinized titanium; precious metal oxide anodes are also used. The available chlorine concentration ranges from 0.2 to 1.0 g/L, and the power consumption is reported to be 5.8 kW h per kg of chlorine.

Seaclor System. The Oronzio de Nora Seaclor system features a bipolar parallel plate-type seawater cell [51] shown in Figure 6. Cathodes are made from titanium and anodes are based on RuO_2. Hypochlorite solutions with an available chlorine content of up to 2.5 g/L are produced; power consumption is cited to be 3.4 – 4.5 kW h per kg of chlorine. The most notable feature of the Seaclor system is the size of the individual cells, which may be large enough to produce nearly 1000 kg/d.

Figure 6. Seaclor hypochlorite cell
a) Inlet; b) PVC cell body with overlay; c) Bipolar electrode; d) Insulator

Pepcon System. The Pepcon system made by Pacific Engineering & Production Co. of Nevada is distinctly different from other commercial cells because it employs less expensive PbO_2 anodes. Pacific Engineering uses a tube-type design, with a steel or titanium pipe form-

ing the outside of the cell and a PbO_2-plated graphite rod at the center. Steel has a small overpotential for hydrogen evolution, but it requires careful protection to prevent corrosion during shutdown.

Maintenance. The major problem of on-site hypochlorite cells, especially those using natural seawater as feed, is that of deposit formation. Because the electrolyte adjacent to the cathode is strongly alkaline, magnesium hydroxide and calcium hydroxide deposit at the cathode surface. If allowed to build up, these deposits may bridge the electrode gap, reducing cell efficiency and ultimately causing anode failure [52].

Most manufacturers of industrial hypochlorite cells will tolerate deposit formation, but simultaneously attempt to minimize the problem by controlling the current density, turbulence, and cathode surface. In the case of seawater the deposit – chiefly $Mg(OH)_2$ – is soft and can generally be scoured from the cathode surface and flushed from the cell by using a high flow rate. Although at least two suppliers suggest that acid cleaning of deposits is never necessary, it seems likely that occasional removal of deposits is required on a cycle that varies from a few days to a few months. Usually, the deposit is removed by flushing the cell with hydrochloric acid. This dissolves the deposit quickly and consumes very little acid. Large industrial installations usually provide for convenient acid washing.

Brine cells may also form deposits as a result of hardness ions introduced from either feed water or from impurities in the salt. In this case, the deposit will usually consist of a hard calcium carbonate, which is also easily removed with acid. Unlike in seawater cells, however, it is often practical to soften the cell feed; brine cells can then be designed to operate with very little deposit formation.

A second major maintenance item is occasional replacement of anodes. The lifetime of both precious metal oxide and platinized titanium anodes is adversely affected by high current density, low salinity, low electrolyte temperature, and severe deposit formation. Manufacturers should be consulted on the expected anode lifetime and cost of replacement. Typically, anodes must be replaced or recoated after 2 – 5 years from startup.

4.3. Storage

Hypochlorite solutions slowly decompose if catalytic amounts of cobalt, nickel, or copper are present; iron and magnesium do not act catalytically [53]. Therefore, long-term storage and transport over long distances must be avoided. Hypochlorite solutions prepared from seawater are especially unstable and should be consumed directly after on-site preparation.

Hypochlorite solutions for household use have an available chlorine concentration of ca. 40 g/L. Special attention must be paid to minimize oxygen evolution. Improper storage of hypochlorite bottles may cause stoppers to be blown out and bottles to explode. Vented stoppers are used to avoid pressure buildup in the bottles.

4.4. Uses

Concentrated hypochlorite solutions are used primarily in the paper and textile industries for bleaching. Since chlorine dioxide (Chap. 5) produces a brighter product and is less harmful to fibers, the use of a hypochlorite solution as bleaching agent in these industries has declined.

On the other hand, the use of electrochemically produced dilute hypochlorite solutions has increased largely over the past several years. Electrolytic generators can be used whenever hypochlorite is needed for disinfection or for bleaching; their advantages are economy, safety, and convenience.

Currently, the broad area of biofouling control accounts for over half of the market for such equipment, especially at locations remote from chlor-alkali plants. The largest seawater electrolysis plants for the production of hypochlorite in the world, a 60 000-kg/d plant in Kuwait and a 48 000-kg/d plant in Saudi Arabia, were commissioned in 1980 as parts of large desalination projects. The hypochlorite is used to control slime and algae in piping and tubes and to eliminate odor in the desalted water.

Another important and quickly growing use for hypochlorite cells is disinfection of seawater for secondary oil recovery; otherwise, slime growth would clog the oil-bearing strata.

The largest plant for this purpose is a 5400-kg/d plant at Qurayyah, Saudi Arabia, where disinfected seawater is filtered, deaerated, and pumped 100 km inland for injection.

Shipboard applications account for many seawater electrolysis installations worldwide. In this case, smaller units are used to inhibit marine growth in seawater systems for sanitary services and for distilled water treatment. Fishing fleets also use hypochlorite as a disinfectant for storage.

Coastal utilities and industrial plants use hypochlorite from seawater electrolysis to control mollusks, algae, and slime, which may block seawater intakes, clog piping, and reduce heat transfer efficiency. Inland utility and industrial plants use brine hypochlorite cells when handling and safety are of primary concern. Nuclear power plants are particularly sensitive to the hazards of liquid chlorine.

Both coastal and inland wastewater treatment plants are major users of chlorine for disinfection before discharge. This was first started on the island of Guernsey in 1966 and was operated for 6 years [54].

On-site hypochlorite production from brine is also used for drinking water treatment, but it is only economical at remote locations or where safety is a major concern.

A number of companies have introduced on-site generators to supply chlorine demand for swimming pools. Many of these have been small chlor-alkali cells with separated anolyte and catholyte; but unseparated hypochlorite generators have gained acceptance and now represent an important portion of that market.

On-site hypochlorite generators are sometimes selected for other less common applications, such as textile manufacturing, industrial and laundry bleaching, cyanide destruction, odor control, ocean aquariums, and food processing [41], [55].

4.5. Economic Aspects

The Middle East now represents about half of the total market for electrolytic hypochlorite generation. The rest of the market is roughly balanced between East Asia, South America, and the United States. The total installed capacity has grown from ca. 200 t/d in 1979 to estimated 700 t/d in 1984. This probably represents total system sales approaching U.S. $\$200\times10^6$ through 1984.

On-site hypochlorite generation is difficult to compare with purchased chlorine or hypochlorite because chemical costs vary widely from nation to nation. Bulk liquid chlorine prices vary from ca. $ 150/t in the United States to well over $ 1000/t in remote locations, and hypochlorite prices vary from $1500/t of available chlorine content in the United States to over $ 2500/t where transportation cost is high. Therefore, a direct economic comparison with purchased chemicals can only be made for each location individually. There are many cases in which the selection of on-site generation is motivated primarily by economics, rather than by safety or convenience.

4.6. Plant Safety

Dilute sodium hypochlorite solution is much safer than liquid or gaseous chlorine. Sodium hypochlorite solution, as produced by on-site electrolytic generators (with an available chlorine content of 0.5 – 10.0 g/L), is regarded as corrosive and as an irritant when ingested or inhaled. It is also a mild skin irritant, and prolonged exposure may result in a burn or rash [56].

The primary safety concern associated with the electrolysis equipment is the explosion and fire hazard from byproduct hydrogen. This hazard is increased if oxygen is present in the cell gas. Oxygen content ranges from 3 % to 9 % in efficiently operating cells, but it varies widely in practice. Cells with anodes having poor selectivity for chlorine evolution or with poor design for operation at low temperature and low salinity may result in an oxygen concentration of 40 % or more in the cell gas.

The explosion limit for hydrogen – oxygen mixtures is 6.0 % O_2. Explosive impact will be soft at this point, but will increase quickly in severity as oxygen content increases. Two measures are taken in commercial cells against this: (1) dilute the byproduct hydrogen with sufficient air to less than 4.0 %, the explosion limit for hydrogen in air, or (2) allow the cell gas to vent with proper precaution, e.g., the installation of rupture disks.

A special hazard arises when cell deposits are washed with dilute hydrochloric acid. In addition to the hazards of handling hydrochloric acid, chlorine gas evolves when HCl is accidentally mixed with stored hypochlorite solution, or when the cells are started without first flushing out the acid.

5. Chlorine Dioxide

5.1. Properties

Chlorine dioxide [*10049-04-4*], ClO_2, M_r 67.45, is a yellowish-green to orange gas. It can be condensed to a reddish-brown liquid at 11 °C and solidified to orange red crystals at − 59 °C. The density of liquid ClO_2 is as follows [57]:

t, °C	− 33	− 21	− 17	5
ϱ, g/cm^3	1.907	1.788	1.735	1.635

Chlorine dioxide has an irritant, pungent odor that resembles that of a mixture of chlorine and ozone. Chlorine dioxide is an extremely unstable gas, readily decomposing into chlorine and oxygen even on mild heating. It is explosive as a gas or liquid at high concentration [58], [59]. However, it can be handled easily when it is diluted with air to less than 15 vol%.

Chlorine dioxide is easily soluble in water (heat of solution: − 26.8 kJ/mol); at 10 °C its solubility in water is 5 times that of chlorine (Table 5).

Chlorine dioxide can be easily driven out of aqueous solutions with a strong stream of air. When an aqueous solution is cooled, $ClO_2 \cdot 8\,H_2O$ crystals precipitate. Chlorine dioxide is also soluble in carbon tetrachloride, sulfuric acid, or acetic acid [61].

Other important properties of chlorine dioxide are its photochemical [62] and thermal [63] decomposition. Solutions of chlorine dioxide are relatively stable in the dark, but they decompose into chlorine and oxygen when exposed to light. Therefore, these solutions are very strong oxidants and extremely reactive and corrosive. They attack all metals except platinum, tantalum, and titanium.

In dilute aqueous solutions, chlorine dioxide oxidizes hydrocarbons to ketones and alcohols [64]. In the absence of water, chlorine dioxide loses its bleaching power.

5.2. Production

Because of the explosion risk, chlorine dioxide is manufactured on site. Its industrial production is based on the reduction of chlorate [65–67]. Undesirable byproducts are chlorine and chloride. For analysis of chlorine dioxide, see [68–71].

Reaction Mechanism [72], [73]. The basic reaction mechanism of chlorine dioxide formation is the same for all known processes. All processes use chlorate as the raw material; in all processes chlorine dioxide formation takes place in strong acidic solutions; and byproduct chloride is found in all generator solutions.

The presence of chloride ions is essential for the formation of chlorine dioxide [74], [75]; this is evident from the following facts:

1) No significant amount of chlorine dioxide is formed in acidified chlorate solutions with various reducing agents when chloride has previously been removed from the reaction system by adding silver sulfate.
2) If chlorine dioxide generators are allowed to stand overnight, minor ClO_2 formation consumes all of the chloride present in the reaction mass. When the supply of fresh raw materials is started the next morning, a specific chloride level must build up before chlorine dioxide can be produced at the desired rate. This chloride buildup phase can be eliminated by deliberately adding fresh chloride to the generator in the beginning.

Independent on the choice of reducing agent, the primary reaction for chlorine dioxide production is the reaction between chloric acid and hydrochloric acid to form chlorine dioxide and chlorine. Traces of Mn^{2+} and Ag^+ ions catalyze the reaction [76].

$$HClO_3 + HCl \longrightarrow HClO_2 + HClO$$
$$HClO_3 + HClO_2 \longrightarrow 2\,ClO_2 + H_2O$$
$$HClO + HCl \longrightarrow Cl_2 + H_2O$$
$$2\,HClO_3 + 2\,HCl \longrightarrow 2\,ClO_2 + Cl_2 + 2\,H_2O$$

In industrial chlorine dioxide production, sulfur dioxide, hydrochloric acid, or methanol are

Table 5. Solubility of chlorine dioxide in water [60]

25 °C		40 °C		60 °C	
p, mbar	*c*, g/L	*p*, mbar	*c*, g/L	*p*, mbar	*c*, g/L

11.2	0.69	13.2	0.47	16.0	0.26

used as reducing agents. Other reducing agents are not economical.

5.2.1. Day – Kesting Process [74], [77], [78]

This process combines the production of chlorine dioxide from sodium chlorate, with hydrochloric acid as reducing agent, and electrochemical sodium chlorate production from sodium chloride:

$$2\,NaCl + 6\,H_2O \xrightarrow{\text{Electrolysis}} 2\,NaClO_3 + 6\,H_2$$
$$2\,NaClO_3 + 4\,HCl \longrightarrow 2\,NaCl + 2\,ClO_2 + Cl_2 + 2\,H_2O$$

The efficiency of chlorine dioxide production depends on how far the rate of the competing chlorine production can be decreased:

$$NaClO_3 + 6\,HCl \longrightarrow 3\,Cl_2 + NaCl + 3\,H_2O$$

This can be achieved by maintaining a high chlorate concentration and a low hydrochloric acid concentration in the reaction system.

Chlorate solution is rapidly circulated from a large storage tank through the electrolytic cells, which oxidize chloride to chlorate. From the same tank the chlorate solution is also circulated slowly through the chlorine dioxide generator. The reaction takes place in a heated multicompartment column. The reactant solutions, chlorate and hydrochloric acid, are added from the top and air is introduced from the bottom of the column [79]. Chlorate is reduced with hydrochloric acid to chlorine dioxide and chlorine. Both gases are stripped from the system with air; at the same time, chlorine dioxide is diluted below the explosion limit [80]. The depleted chlorate solution is then returned to the storage tank and recycled to the chlorate electrolysis. The mixture of chlorine dioxide and chlorine is stripped with water to give a solution rich in chlorine dioxide [80], [81] and a gas phase rich in chlorine. Chlorine can then be recycled to the process as hydrochloric acid by reduction with hydrogen produced in the electrolytic cells or neutralized with NaOH solution to produce hypochlorite.

Although it has always been cheaper to produce chlorine dioxide by this process, it never gained momentum because of the high initial capital expenditure involved.

Lurgi [79], [82–86], Chemetics [87], [88], and others [89–91] have developed integrated systems that combine this process with the production of chlorine, caustic soda, and hydrochloric acid. Such combined systems use sodium chloride and electric power as the raw materials and produce chlorine dioxide solution and caustic soda (Fig. 7).

5.2.2. R2 Process [92–100]

Hooker Chemical Corporation, together with Electric Reduction Company, developed the R2 process, starting from the single-vessel process [101–103], and Electric Reduction Company further improved the details. Chlorine dioxide is produced according to the following overall reaction:

$$2\,NaClO_3 + 2\,NaCl + 2\,H_2SO_4$$
$$\longrightarrow 2\,ClO_2 + Cl_2 + 2\,Na_2SO_4 + 2\,H_2O$$

An undesirable side reaction produces additional chlorine:

$$NaClO_3 + 5\,NaCl + 3\,H_2SO_4$$
$$\longrightarrow 3\,Cl_2 + 3\,Na_2SO_4 + 3\,H_2O$$

In continuous industrial processes, the molar ratio of chlorine dioxide to chlorine is nearly 2 : 1, indicating that the ClO_2 production efficiency is almost 100 % (based on chlorate).

Figure 7. Schematic diagram of the integrated Day – Kesting process [82]
a) Chlorine stripper; b) Sodium chlorate solution; c) Chlorine dioxide solution storage; d) Chlorine dioxide generator; e) Chlorate electrolysis; f) Hydrochloric acid furnace; g) Hydrochloric acid storage

Figure 8. Schematic diagram of the R2 process [104]

Figure 8 shows a schematic diagram of the R2 process. Concentrated solutions of sodium chlorate, sodium chloride, and sulfuric acid (equimolar ratio) are metered to a vigorously agitated reaction vessel. Air is blown into the reactor through porous plates. Under optimum conditions, the reaction mass contains 0.1 – 0.2 mol/L of sodium chlorate, 4.5 – 5 mol/L of sulfuric adic and 0.02 – 0.08 mol/L of sodium chloride. Chlorine dioxide is absorbed from the gas phase in packed towers in cold water, and chlorine leaves the system as byproduct. The liquid effluent from the reactor is a mixture of sodium sulfate and sulfuric acid. The process can also be operated in such a way that sodium hydrogen sulfate crystallizes from the effluent solution [105], [106]. It provides sulfate for kraft pulping; the sulfuric acid is recovered for reuse.

The R2 process has been modified [106] and optimized [103], [107], [112] to suit the require-

ments of the industry. Currently, it is probably the most extensively used process for the production of chlorine dioxide.

5.2.3. Mathieson Process [67], [74], [96], [98], [104]

Sulfur dioxide is the reducing agent in the Mathieson process. The main overall reaction is as follows:

$$2\,NaClO_3 + H_2SO_4 + SO_2 \longrightarrow 2\,ClO_2 + 2\,NaHSO_4$$

Solutions of sodium chlorate and sulfuric acid are added continuously to a relatively large, cylindrical, lead-lined tank (primary reactor) from the top. Sulfur dioxide, diluted with air, is introduced through gas diffusion plates at four points in the bottom of the tank. The reaction mass overflows to a smaller secondary reactor of similar construction. The generated chlorine dioxide still contains some unreacted sulfur dioxide; it is stripped from the reaction mass by air and then washed in a scrubber packed with Raschig rings. The scrubber is installed on top of the primary generator, and the fresh sodium chlorate solution serves as a washing liquid on its way down to the primary generator. The mixture of chlorine dioxide, air, and chlorine coming out of the scrubber goes to the absorption tower.

5.2.4. Solvay Process [67], [74], [96], [98], [113]

The Solvay process uses methanol as reducing agent. The main overall reaction is as follows:

$$2\,NaClO_3 + CH_3OH + H_2SO_4 \longrightarrow 2\,ClO_2 + HCHO + Na_2SO_4 + 2\,H_2O$$

The reaction between sodium chlorate, methanol, and sulfuric acid takes place in two jacketed, lead-lined steel reactors. The chemicals are added to the bottom of the first vessel and flow by gravity from one reactor to the other. Each vessel has its own supply of methanol and air. The two reactors are operated at different temperatures and chlorate concentrations. Up to 70 % of the reaction is completed in the first reactor. Additional methanol and up to 10 % of the total acid requirement is fed to the second reactor; the conversion of chlorate is then more than 95 %.

5.2.5. Other Processes

The *Holst process* [114–116] is a batch version of the Mathieson process and has not been exploited because of its low chlorine dioxide yield. When solid sodium chlorate is successively added, the unreacted sulfuric acid from the previous operating period can be utilized and the conversion efficiency of chlorate increases to 83 %.

The *Persson process* [74], [117] has only historical value. The main raw materials were sodium chlorate and sulfur dioxide, but the latter was used to reduce chromic acid to chromic sulfate, and this in turn reduced chlorate to chlorine dioxide.

The *CIP process* [118], [119] was in operation long before it was published, maintaining secrecy for several years. Concentrated sodium chlorate solution is carefully metered and distributed to a packed reaction tower. Sulfur dioxide gas, diluted with air or nitrogen, enters from the bottom, reacts with the chlorate, and is oxidized to sulfuric acid. Chlorate is reduced to chlorine dioxide. The additional inert gas dilutes the ClO_2 formed to a safe concentration, and the mixture is led to the absorption tower.

Small-Scale Production from Sodium Chlorite [120–123]. Small-scale consumers produce chlorine dioxide by passing chlorine gas through a sodium chlorite solution:

$$2\,NaClO_2 + Cl_2 \longrightarrow 2\,NaCl + 2\,ClO_2$$

The reaction is almost quantitative.

The alternative acidification of sodium chlorite solution with hydrochloric acid is also commonly used:

$$5\,NaClO_2 + 4\,HCl \longrightarrow 4\,ClO_2 + 2\,H_2O + 5\,NaC$$

5.3. Economic Aspects

The economy of chlorine dioxide production depends on the efficient utilization of the byproducts of the process [97], [105]. When the chlorine dioxide production is combined with chloralkali membrane cells and hydrochloric acid

synthesis (Lurgi concept), chlorate cells work most efficiently [82–90]. Byproducts from one unit can then be used as raw materials or make-up chemicals for the others. In this way, high initial capital cost is paid back in the long run by a far lower operating cost. The R2 process offers similar possibilities if it is combined with a paper mill [95], [107], [111].

5.4. Uses

Chlorine dioxide is the most widely used bleaching agent, in particular for high-quality cellulose. It destroys lignin without attacking cellulose, yielding a characteristically white cellulose. The general trend is to eliminate chlorine and hypochlorite as bleaching agents altogether [124], [125] and replace them with chlorine dioxide [81], [126], [127].

Chlorine dioxide is used in the pulp and paper, textile, and food industries. In the pulp and paper industry, a unique whiteness can be achieved in kraft pulp, sulfite pulp, and soda pulp [96]. In the textile industry, chlorine dioxide produces high-quality fibers with additional special advantages. Shrinkproof wool owes its quality to the reaction of chlorine dioxide with the cross-linking sulfur atoms of the wool.

Chlorine dioxide is also used in sanitization, e.g., of industrial and municipal waters, sewage, algae, or decomposed vegetables. Waterworks use chlorine dioxide to handle taste and odor problems of household water [68], [122], [123], [128].

6. Sodium Chlorite

6.1. Properties

Sodium chlorite [*7758-19-2*], $NaClO_2$, M_r 90.45, is the sodium salt of the unstable chlorous acid; it exists as an anhydrous and a trihydrated form (transition point 38 °C). Very pure $NaClO_2$ crystals are white, but they usually have a greenish tint because traces of chlorine dioxide are present.

The stability of sodium chlorite lies between that of hypochlorite and chlorate. For further information, see [129]. Sodium chlorite is not sensitive to impact if organic matter is excluded. It can be struck with a clean metal surface without detonation. However, in the presence of organic matter – the film usually occurring on a hammer suffices – the impact may result in a spontaneous puffing. As a strong oxidizing agent, solid sodium chlorite forms explosive mixtures with such oxidizable materials as sulfur, powdered coal, metal powders, or organic compounds. Sodium chlorite solutions should never be allowed to dry on fabrics because this would result in a flammable combination.

Sodium chlorite is soluble in water: [129]

t, °C	5	17	20	30	40	45	50	60
Solubility, wt %	34	39	40.5	46	50.7	53	53.7	55

More important is its solubility in the presence of caustic soda (Table 6), sodium chlorate [130], sodium chloride, [131], and sodium carbonate [132]. For the system $NaClO_2 - NaCl - NaClO_3 - H_2O$, see [133], [134].

Aqueous solutions of sodium chlorite must be protected from light. At low pH (approximately 2), chlorite solutions contain chlorous acid that decomposes to form chlorine dioxide and chlorate:

$$4\,HClO_2 \longrightarrow 2\,ClO_2 + HClO_3 + HCl + H_2O$$

At pH 3 – 4, decomposition slows down. Alkaline solutions are stable, and dilute solutions can even be boiled without decomposition. Concentrated alkaline solutions of sodium chlorite slowly decompose when heated [135–137]:

$$3\,NaClO_2 \longrightarrow 2\,NaClO_3 + NaCl$$

The reaction of sodium chlorite with hypochlorite depends on pH [137]. At low pH, the reaction produces chlorine dioxide, whereas at high pH, chlorate is formed. The reaction with chlorine produces chlorine dioxide and sodium chloride:

$$2\,NaClO_2 + Cl_2 \longrightarrow 2\,ClO_2 + 2\,NaCl$$

Crystalline sodium chlorite is slightly hygroscopic without caking; it is stabilized with alkali for long-term storage. When heated to 180 – 200 °C, it decomposes partially to sodium chlorate and sodium chloride or completely to sodium chloride and oxygen [129]. For the analysis of sodium chlorite, see [69], [70], [138–140].

6.2. Production

Sodium chlorite is produced by treating chlorine dioxide with caustic soda [141–143]:

$$2\,ClO_2 + 2\,NaOH \longrightarrow NaClO_2 + NaClO_3 + H_2O$$

The reaction products, sodium chlorite and sodium chlorate, have nearly the same solubility in water and are difficult to separate. Industrial sodium chlorite production uses the following procedure [144]. The absorption of chlorine dioxide in caustic soda solution and the simultaneous reduction of chlorate to chlorite are achieved by a suitable reducing agent, such as hydrogen peroxide [145]:

$$2\,ClO_2 + 2\,NaOH + H_2O_2 \longrightarrow 2\,NaClO_2 + 2\,H_2O + O_2$$

The product is a 33 wt % solution of sodium chlorite, which is then converted to a dry solid containing ca. 80 wt % of sodium chlorite, the rest being stabilizers.

Numerous complex chlorites have been prepared [146], but only sodium chlorite has proven to be of any commercial value.

Efforts to produce sodium chlorite by electrolysis, similar to hypochlorite or chlorate, have not yet been successful. Its synthesis from chlorine dioxide and sodium amalgam [147] could not be realized because redox potential [148] and pH [149] were difficult to control. Other processes for the direct reduction of chlorine dioxide were not efficient [150], [151].

6.3. Uses

Sodium chlorite is a very efficient bleaching agent. Its oxidation potential allows a controlled bleaching that is not attainable with other bleaching agents. Therefore, it is widely used as a bleaching agent in the textile industry [135–137], [152–155].

Another important use of sodium chlorite is the small-scale production of chlorine dioxide; see Section 5.2.5 [120–123].

7. Chloric Acid and Chlorates

Chloric acid is not being produced on an industrial scale. However, sodium chlorate and potassium chlorate have outstanding industrial significance. Sodium chlorate is produced on a very

large scale by one of the most important inorganic electrosyntheses. All other chlorates are produced in much smaller amounts for special purposes, usually from sodium chlorate.

Table 7. Physical properties of sodium chlorate and potassium chlorate

7.1. Properties

Physical Properties. Anhydrous *chloric acid* [*7790-93-4*], $HClO_3$, M_r 84.46, is unstable and explosive. Dilute aqueous solutions are colorless and odorless; they are stable at low temperature if catalytically active contaminants are excluded. In the presence of such catalysts, the solutions may decompose vehemently, particularly at elevated temperature. Addition of polyphosphates or hydrogen peroxide lowers the decomposition tendency. Above 95 °C, pure chloric acid solutions decompose to form chlorine dioxide, chlorine, oxygen, and perchloric acid, but in the presence of hydrochloric acid, the products are chlorine and chlorine dioxide.

Concentrated chloric acid is a strong oxidant. In addition to the noble metals, only Hastelloy C exhibits satisfactory resistance against corrosion. At low temperature, dilute chloric acid may be kept in containers made of poly(vinyl chloride). At 18 °C, the density of an aqueous 13 % $HClO_3$ solution is 1.080 g/cm^3 while that of a 25 % solution is 1.166 g/cm^3.

Figure 9. Densities of aqueous solutions of NaCl – $NaClO_3$ and KCl – $KClO_3$ [156]
$\Sigma\zeta$ is the sum of mass ratios $\zeta_{chloride}$ (kg of chloride/kg of H_2O) and $\zeta_{chlorate}$ (kg of chlorate/kg of H_2O)

Physical properties of *sodium chlorate* and *potassium chlorate* are shown in Table 7. Figure 9 shows the densities of aqueous chloride – chlorate solutions. Figure 10 shows the relative vapor pressure depression of aqueous solutions of chloride and chlorate. The electric conductivity of pure chlorate solutions is given in Table 8; for further data, see [158]. Solubility data of the aqueous chloride – chlorate system are shown in Figures 11 and 12 and in Table 9. The mass fraction of saturated sodium chlorate solutions in the range from 0 to 100 °C can be calculated from

$$w = 0.445 + 0.00226t$$

where

t = temperature, °C
w = mass fraction, kg of $NaClO_3$/kg of solution

The freezing point depression ΔT (in K) of aqueous solutions of sodium chlorate is given by

$$\Delta T = 33.64\zeta - 115.1\zeta^2$$

where ζ = mass ratio, kg of $NaClO_3$/kg of H_2O

Figure 10. Vapor pressure depression of aqueous chloride and chlorate solutions

Figure 11. Solubility of aqueous solutions of NaCl and $NaClO_3$ [159]

Figure 12. Solubility of aqueous solutions of KCl and $KClO_3$ [159]

Chemical Properties. Chlorates decompose to yield oxygen. They form flammable and explosive mixtures with organic substances, phosphorus, ammonium compounds, some sulfur compounds, and some metal salts, oxidizable solvents, or other oxidizable substances. Potassium chlorate decomposes below the melting temperature. Alkaline chlorate solutions do not exhibit strong oxidizing properties. With decreasing pH, however, the oxidizing activity of chlorate solutions increases. Concentrated acidic solutions are vigorous oxidants as a result of chloric acid formation.

Solutions containing more than 30 % $HClO_3$ decompose spontaneously. In the presence of organic matter or reducing agents the reaction may be violent, especially at elevated temperature.

7.2. Production Fundamentals

Sodium chlorate (and to a minor extent potassium chlorate) is produced by electrolysis of an aqueous sodium chloride (potassium chloride) solution. Hypochlorite forms as an intermediate that is further oxidized to chlorate along two competing reaction paths. The concentrated chlorate solution is either submitted to crystallization (see Section 7.4) or it is used directly, particularly in the production of chlorine dioxide.

An aqueous solution containing 450 – 550 g/L of sodium chlorate and 90 – 100 g/L of sodium chloride is generated directly by electrosynthesis; it can be used as feed in the Kesting process (Section 5.2.1) [160]. The spent solution from that process, containing 140 g/L of sodium chlorate and 220 g/L of sodium chloride, is then fed back to the electrolysis system.

The other, less common chlorates are chemically formed by conversion of sodium chlorate with the corresponding chloride. Other production methods, such as the chemical formation of chlorates by introducing gaseous chlorine into a warm hydroxide solution, are now obsolete.

7.2.1. Chlorate-Generating Reactions

An aqueous solution of sodium chloride is electrolyzed, usually in cells without a diaphragm.

Table 8. Electric conductivity of pure sodium chlorate solutions [157]

Hydrogen and sodium hydroxide are formed at the cathode, while chloride is discharged at the anode. Chlorine does not evolve as a gas, but undergoes hydrolysis (Fig. 13):

$$Cl_2 + H_2O \rightleftharpoons HClO + H^+ + Cl^- \quad (4)$$

Chlorate then forms simultaneously by two competing reactions: (1) predominantly by autoxidation of hypochlorite in the bulk electrolyte, and (2) to a small extent (ca. 20 %) by anodic chlorate formation. The detailed mechanism of the reaction was essentially clarified at the turn of the century, but continues to be the subject of intense studies [39, b].

Autoxidation. Autoxidation of hypochlorous acid, also called chemical chlorate formation, is a homogeneous reaction that proceeds according to the following overall equation, which gives no information on the individual steps:

$$3\,HClO \longrightarrow ClO_3^- + 2\,Cl^- + 3\,H^+ \quad (5)$$

Autoxidation is preceded by dissociation of a part of the total hypochlorous acid involved in autoxidation:

$$HClO \longrightarrow ClO^- + H^+ \quad (6)$$

This dissociation can occur to a significant degree only at some distance from the anode, where the electrolyte is sufficiently buffered by hydroxyl formed by the cathode reaction. The hypochlorite formed then reacts with the complementary amount of hypochlorous acid:

$$2\,HClO + ClO^- \longrightarrow ClO_3^- + 2\,Cl^- + 2\,H^+ \quad (7)$$

Equation (7) shows the classical form of Foerster [161], [162], which was attacked [163] but has since been confirmed [164], [165].

Anodic Chlorate Formation. The mechanism of anodic chlorate formation was established by Landolt and Ibl [166]. Hydrolysis of chlorine (Eq. 4) is considered to be fast. Because of the formation of H^+ ions, one might expect the electrolyte in the anodic boundary layer to be strongly acidic. However, this is the case only at low chloride concentration. Large chloride concentrations, as they occur in industrial processes, shift the hydrolysis equilibrium (Eq. 4) to the left. In the electrolyte layer adjacent to the anode, the H^+ concentration is too small to permit noticeable diffusion of H^+ into the inner electrolyte. Therefore, hydrogen is transported away from the anode as hypochlorous acid rather than H^+. In the bulk electrolyte where the pH is high, hypochlorous acid is largely dissociated. The hypochlorite ion diffuses back to the anode

Figure 13. Chlorate formation by autoxidation in bulk electrolyte and by anodic oxidation

and more than two-thirds of it is consumed by buffering before reaching the anode. However, less than one-third of that hypochlorite is discharged at the anode to form chlorate and oxygen [166–168]:

$$3\,ClO^- + 1.5\,H_2O \longrightarrow ClO_3^- + 3\,H^+ + 2\,Cl^- + 0.75\,O_2 + 3\,e \qquad (8)$$

The stoichiometry of the anodic chlorate formation (Eq. 8) was recently reviewed [39, b].

As shown in Figure 13 the discharge of 6 mol of chloride yields 1 mol of chlorate; this is independent of the reaction route, either autoxidation or anodic discharge of hypochlorite. However, the anodic oxidation (Eq. 8) requires 50 % additional electric energy. Therefore, industrial processes endeavour to suppress the anodic oxidation in favor of the autoxidation. The effective means is a short residence time of the electrolyte solution inside the electrochemical reactor by applying large flow rates using rather short electrode lengths. Thereby the average bulk concentration of hypochlorite ($ClO^- + HClO$) is lowered and the undesired anodic chlorate formation controlled by mass transfer is minimized. However, increasing flow rates increase the mass transfer coefficient, thus counteracting the beneficial effect of short residence time. The optimum is at elevated values of the flow rate; this method to suppress anodic oxidation is used in all modern industrial chlorate systems. Under these conditions, chlorate is formed predominantly outside the interelectrode space, e.g., in a separate chemical reactor where the route is necessarily restricted to autoxidation (Fig. 14).

Figure 14. Concept of separate electrochemical reactor (a) and chemical reactor (b) for chlorate electrosynthesis

7.2.2. Loss Reactions

In addition to anodic chlorate formation, further loss reactions decrease current efficiency and must be suppressed in industrial systems.

Cathodic Reduction of Hypochlorite. The main loss occurs by cathodic reduction of hypochlorite, as described in Section 4.2.1:

$$ClO^- + H_2O + 2\,e \longrightarrow Cl^- + 2\,OH^-$$

The reaction competes with hydrogen generation. Without special precautions, its rate is controlled by mass transfer and, therefore, linearly proportional to the hypochlorite concentration in the bulk electrolyte. The reaction can widely be suppressed by adding a small amount of dichromate (1 – 5 g/L) to the electrolyte solution. By cathodic deposition a porous surface film of chromium hydroxide forms [169]. Inside

the pores of this film, the effective current density increases, and the resulting potential gradient across the film impedes the diffusion of any kind of anions to the cathode, whereas the access of cations to the cathode and their reduction are facilitated. The protective film ceases to grow after a certain thickness is reached; the increase in cell voltage caused by the ohmic resistance of the film is more than compensated by the gain in current efficiency [165], [170]. Increasing the electrolyte temperature favors mass transfer of hypochlorite to the cathode and, therefore, requires more dichromate. When the current is interrupted, the surface layer dissolves. It takes some time to reestablish a new film after the current is switched on, but cathodic reduction immediately takes place. Therefore, cells should be operated continuously, and a minimum cathodic current density is recommended to prevent dissolution of the film [171]; from industrial experience, a current density of 20 A/m^2 is considered satisfactory.

Cathodic Reduction of Chlorate. Chlorate is also reduced at the cathode, but this reaction is less significant than the reduction of hypochlorite described in the preceding paragraph:

$$ClO_3^- + 3\,H_2O + 6\,e \longrightarrow Cl^- + 6\,OH^-$$

The rate of reduction is strongly affected by the cathode material; reduction at iron is much faster than at nickel and platinum. Chlorate reduction is also restrained by the chromium hydroxide layer on the cathode [16], [171–174]. In closed-loop electrolyte systems (e.g., Fig. 14), the presence of residual dichromate in the solution has a beneficial effect because its additional buffering capacity stabilizes the various reaction equilibria [165], [175], [176].

Catalytic Decomposition of Hypochlorite. Hypochlorite solutions decompo e in the presence of catalytically active contaminants:

$$2\,ClO^- \longrightarrow 2\,Cl^- + O_2$$

Oxides of nickel, cobalt, and copper are very effective; their catalytic activity decreases in that order. The catalytic action of manganese, iron, lead, and tin has been demonstrated, but is at least one order of magnitude smaller [53], [177]. Autocatalytic decomposition is also possible, but its extent is negligible at ambient temperature [177], [178].

Chlorine Desorption. Hydrogen and oxygen gas bubbles evolved at the cathode and anode, respectively, tend to desorb some chlorine from the solution. This amount of chlorine is lost for chlorate production unless it is recovered from the cell gas by absorption outside the cell. Water vapor contained in the gas bubbles increases their volume and, thus, the desorption loss. Therefore, the operation temperature is limited to a maximum of 80 – 90 °C. Chlorine loss results not only in a corresponding loss in current efficiency, but also in a steady increase in pH. Therefore, chlorine gas or, more usually, hydrochloric acid must be permanently added to maintain the pH.

Further loss reactions are of minor importance: *perchlorate* may be formed by anodic oxidation of chlorate, particularly at low chloride concentration, provided the oxygen overvoltage is large enough (see Section 8.2.2). With the industrial anodes used in chlorate electrosynthesis, perchlorate formation is negligible. The *anodic decomposition of water,* which plays a major role in hypochlorite production, is negligible as long as the chloride concentration is larger than 100 g/L.

Figure 15. Huron electrosynthesis system with integrated electrolysis cells
a) Chemical reactor; b) Cooling coils

7.3. Industrial Electrosynthesis Systems

Chlorate cell design has changed much within the last 25 years by the introduction of coated titanium anodes [179] and by the systematic application of the results of chlorate formation theory. Hypochlorite autoxidation occurs at high temperature outside the interelectrode gap or even outside the electrochemical reactor to decrease the hypochlorite concentration before the electrolyte reenters the cell. The first industrial plant of this type was started in 1969 in Finland.

Figure 16. Electrosynthesis system with natural convection of electrolyte (Krebs, Paris)
a) Electrolysis cell; b) Chemical reactor; c) Cooler

The requirement for large electrolyte flow rate resulting from the considerations of Section 7.2 is taken into account in all modern cells. Hydrogen evolved at the cathode provides for a natural flow of the electrolyte and is used for its recirculation through the cell compartment and the chemical reactor without requiring additional pumping. Other systems use a mechanical pump to provide the required circulation rate. Hydrogen gas is released at the top of the unit. For safety reasons, the gas volume in the equipment must be minimized. To stabilize the pH value, the solution is continuously acidified (cf. Section 7.2.2.).

Some electrosynthesis systems combine the cell and the chemical reactor in a single unit (Huron, Fig. 15, and Atochem). Other industrial systems are composed of an electrochemical reactor and a separate chemical reactor [180] interconnected by electrolyte circulation pipes with integrated heat exchangers for the removal of excess heat (Krebs, Fig. 16, and Pennwalt, Fig. 17) or separate heat exchangers (Krebskosmo, Chemetics, and Fröhler – Lurgi – Uhde). None of these electrosynthesis systems is clearly superior from an engineering point of view.

7.3.1. Electrolysis Cell Types

Most cells are equipped with coated titanium anodes [181], and only some 5 – 10 % of all chlorate cells still use graphite anodes. Older cells have also been operated with anodes of magnetite (Fe_3O_4) [182], [183], platinum [184], graphite [185–188], or lead dioxide [189], [190]; reviews on these older anodes can be found in [39] and [191–193]. The following survey is restricted to modern cells with coated titanium anodes. Typical operational data are shown in Table 10.

Modern electrochemical reactors [194–196] cover the complete spectrum of unipolar and bipolar electrodes, including direct coupling of cells with unipolar electrodes, an arrangement sometimes called multipolar (Fig. 18).

Cells with *unipolar* electrodes (Krebs, Pennwalt, Fröhler – Lurgi – Uhde, and Atochem) are suitable for large currents up to 100 kA. Repair of one cell does not necessitate shutdown of the entire electrolyzer. Parasitic currents [197], corrosion, and malfunction of a cell unit are easy to locate. Pennwalt and Atochem use two cathodes per anode. This design allows circulation within the cell [194], [195]. Cells with *bipolar* elec-

trodes (Krebskosmo) seldom exceed 30 kA (in charge of the voltage), thus lowering the rectifier cost. *Multipolar cells* (Chemetics and Huron) combine some of the advantages of cells with unipolar and bipolar electrodes and require a minimum of bus bars, resulting not only in savings in investment cost, but also in cell voltage. However, the entire electrolyzer system must be shut down for repair of a single unit.

7.3.2. Electrodes

Anodes. N. B. Beer made a decisive breakthrough in anode technology in the mid-1960s by introducing anode coatings based on ruthenium dioxide, RuO_2 [15], [198–201]. In fact, the anode surface is composed of a mixture of RuO_2 with other metal oxides, primarily titanium dioxide. These anodes maintain a low overvoltage for chlorine formation at high current densities for long periods without being consumed and changing their mechanical dimensions. Independent of the detailed nature of the mate-

Figure 18. Directly connected electrochemical reactors (multipolar arrangement, Chemetics)

rial, they are called *dimensionally stable anodes* (DSA) (→ Chlorine) [202–204]. In the chlorate field, dimensionally stable anodes have been selected for 80 % of the total capacity installed since 1978.

Sintered titanium anodes (STA) have been developed by Sigri. In these electrodes, an intermediate layer of sintered titanium suboxide is applied between the titanium substrate and the coating, which gives improved mechanical stability, excellent adhesion to sintered titanium structures, and increased active surface area [205], [206]. Imperial Chemical Industries (ICI) has used these anodes in large-scale production since 1971. Other novel anodes have been developed by Imperial Metal Industries (IMI) and Marston Excelsior (Marex Electrode).

Titanium anodes normally consist of 1.5 – 4-mm sheets or of expanded mesh, activated by platinum group metal oxides. In troublefree operation, the durability of the coating based on ruthenium dioxide [207] is between 6 and 10 years. The literature on coated titanium anodes for chlorate electrosynthesis is reviewed in [193].

Cathodes. Mild steel has been the industrial standard for many years. It has a low hydrogen overvoltage and is cheap and stable under the operating conditions. However, steel corrodes when the cells are shut down, and it absorbs hydrogen, which tends to make the metal brittle and to form fissures in the welding areas and blisters [208]. The cathodes are usually 3 – 8 mm thick. The sheets are often perforated with holes of 3 – 6 mm diameter or they are slotted, which facilitates the release of hydrogen bubbles from the interelectrode gap. Mild steel cathodes tend to collect carbonate deposits, which increase the potential of the cathodes. This requires periodic acid washing unless the process water is deionized to contain less than 0.05 mg/kg of impurities.

The application of steel cathodes in bipolar cells is complicated because dissimilar metals must be joined. However, no connection problems arise by explosion bonding of titanium and steel [209].

Attempts to coat the steel cathodes or to replace them by other metals have not brought satisfactory results. Titanium has not been generally accepted because of its tendency to form titanium hydride, TiH_2, which gradually makes the cathode break off and limits the lifetime to 2 years. Attempts to lower the overvoltage by coating the cathodes with nickel, molybdenum, or their oxides [210] have not yet been successful because these materials catalyze the decomposition of hypochlorite during shutdown. Cathodes made from titanium alloys, e.g., Ti – 0.2 % Pd , remain stable for 2 years at a temperature of 95 °C, whereas the durability is much longer at 75 °C.

7.3.3. Operational Parameters

Temperature. The operation of electrochemical reactors benefits from temperature increase in two ways: (1) the cell potential decreases by lowering the resistivity of the electrolyte, and (2) autoxidation of hypochlorite to chlorate is more strongly favored than anodic oxidation. Consequently, the current efficiency increases with temperature. On the other hand, the temperature should not be near the boiling temperature of the electrolyte because then the rate of chlorine and water desorption increases. The introduction of dimensionally stable metal anodes has permitted raising the operating temperature from 40 – 45 °C (previously with graphite anodes) to 80 – 90 °C.

Pressure. Increasing the electrolyte pressure lowers not only the rate of chlorine desorption, but also the volume of the gas bubbles released from the electrolyte; thus, it acts favorably on the interelectrode resistivity. However, serious engineering problems arise when the pressure is increased. Industrial electrochemical reactors are usually operated at a gage pressure of less than 0.1 MPa (1 bar).

Interelectrode Distance. The electric interelectrode resistance strongly depends on the quantity of gas bubbles dispersed in the electrolyte [211]. When the electrolyte flow rate is increased and the electrode distance decreased, the resistance decreases. However, a very small electrode distance leads to a large frictional pressure drop in the reactor. Therefore, the minimum spacing of industrial reactors is ca. 3 mm, which roughly agrees with the results of optimizations [212]; distances of 3 – 5 mm are generally used between metal electrodes.

pH Value. According to Equation (7) (see Autoxidation, page 24), autoxidation of hypochlorite requires the simultaneous presence of hypochlorous acid and hypochlorite. The concentration of both species is very dependent on pH. A carefully controlled pH value, therefore, is a prerequisite of an industrially acceptable current efficiency. The optimum pH depends on the temperature and is maintained in the range of 6.1 – 6.4 in modern industrial electrochemical reactors operated at 80 – 90 °C.

Chloride Concentration. The brine feed to the cells is always close to being saturated to obtain a large final chlorate concentration of the product solution. The chloride concentration should not fall below 80 – 100 g/L because water decomposition is favored at low chloride concentration [213]. If necessary, the brine is resaturated with salt, but solubility limits must be observed (Figs. 11 and 12).

Current Density. High current density increases the acidity near the anode, thus depressing anodic hypochlorite oxidation. In addition, cathodic hypochlorite reduction is hampered. However, current density of industrial cells is limited by the concurrent increase in cell potential. Current densities of industrial cells are optimized on the basis of these considerations and thus permit operation at higher current efficiencies.

Current Efficiency. If x is the fraction of the hypochlorous acid (or chlorine) involved in the anodic oxidation and $(1-x)$ is the fraction that produces chlorate along the autoxidation reaction, the current efficiency ε is (cf. Fig. 13)

$$\varepsilon = \frac{1}{1 + 0.5x} \tag{9}$$

Exclusive anodic chlorate formation would result in a current efficiency of $\varepsilon = 66.7$ %, provided the contribution of loss reactions is negligible. The short survey of the operational parameters given in the previous sections highlights the complex system that governs current efficiency in chlorate electrosynthesis. The problem has been dealt with in detail in [39] and is the object of methodical investigations [215], [216]. Mathematical models have been established to provide means to theoretically predict current efficiency. A model assuming ideal stirred-tank-reactor conditions for both the electrochemical and the chemical reactor [214] was compared with industrial results [180]. A more recent model combines a plug flow electrolyzer with either a stirred tank or a plug flow chemical reactor [217]. The results show satisfactory agreement with data from two industrial systems [218].

The current efficiency of operating industrial cells with external recirculation of the electrolyte (Fig. 14) can be assessed by measuring the difference Δc of total hypochlorite concentration (mol/L) at the cell outlet and inlet. Because the difference of total hypochlorite concentration represents the amount of hypochlorite converted to chlorate by autoxidation outside the cell, the current efficiency is calculated to be

$$\varepsilon = \frac{2}{3}\left[1 + \frac{\dot{V}_L \cdot \Delta c \cdot F}{I}\right] \tag{10}$$

where

F = Faraday constant (96 487 A s/mol)
$\dot{V}_L$ = volume flow rate, m^3/s
I = total current, A

Equation (10) does not take account of the autoxidation in the interelectrode gap, and it neglects all loss reactions; both factors tend to balance.

In all electrosynthesis systems, including those without external electrolyte recirculation, the current efficiency may be estimated by analyzing the gas mixture leaving the electrochemical reactor. The amount of anodic chlorate formation (together with the catalytic decomposition) can be assessed from the volume fraction of oxygen (φ_{O_2}). The loss caused by chlorine desorption is represented by the volume fraction of chlorine (φ_{Cl_2}). Moreover, the ratio of the true hydrogen flow rate N_{H_2} to the flow rate N'_{H_2} as calculated from Faraday's law indicates the loss through cathodic reduction of hypochlorite and chlorate [219]:

$$\varepsilon = \frac{1 - 3\varphi_{O_2} - 2\varphi_{Cl_2}}{1 - \varphi_{O_2} - \varphi_{Cl_2}} \cdot \frac{N_{H_2}}{N'_{H_2}} \tag{11}$$

In industrial operation, the current efficiency is predominantly lowered by anodic chlorate formation; when neglecting any other loss reaction, one obtains a very simple approximation equation:

$$\varepsilon \approx 1 - 2\varphi_{O_2} \tag{12}$$

The error of Equation (12) as compared to Equation (11) is within the accuracy of gas analysis in the current efficiency range of modern cells. Automatic measurement of the oxygen concentration in the cell gas, therefore, serves as a simple and reliable means to control cell operation.

7.3.4. Brine Purification

Solar salt from seawater, rock salt, or very pure "vacuum salt" are used as raw material. The brine must not contain large amounts of magnesium and calcium, which could form deposits on the cathodes. Sodium carbonate and sodium hydroxide are added to the brine to raise its pH to at least 10. The sulfate concentration must be lower than 10 – 20 g/L. The brine must be free of heavy metals that favor the decomposition of hypochlorite (see Section 7.2.2). Maximum impurity concentrations are listed below:

SO_4^{2-}	10 g/L
SiO_2	10 mg/kg
Al, $P_2O_7^{4-}$, Ca	5 mg/kg
Fe, Mn, Sn	1 – 5 mg/kg
Cu, Mg, Pb, Ti	1 mg/kg
Cr, Mo	0.5 mg/kg
Ir, Co	0.2 mg/kg
Ni	0.05 mg/kg

7.4. Crystallization

For the crystallization of chlorate, a solution of 560 – 630 g/L of sodium chlorate and 90 – 120 g/L of sodium chloride is produced at 70 – 90 °C. The temperature at the cell outlets is

first raised to 85 – 95 °C to convert the remaining 1.5 g/L of hypochlorite into chlorate. Urea, ammonia, hydrogen peroxide, or sodium formate is added to complete the hypochlorite decomposition. The solution is then rendered slightly alkaline with NaOH; this reduces corrosion in the crystallizer. The $NaClO_3$ solution is subsequently fed to a vacuum crystallizer, based on flash cooling with subsequent crystallization.

Crystalline chlorate is separated from sodium chloride solution by cooling or evaporation [220]. Crystallization conditions depend on the concentration of NaCl and $NaClO_3$, on solution temperature, and on mixing intensity. The cooling rate has little influence on the crystal size; ca. 90 % of the crystals have 120 – 260 µm diameter. The solution temperature, initially raised to 90 – 95 °C, drops to 48 °C in the separator and to 35 °C in the vacuum crystallizer at 2.9 kPa. The concentrated slurry contains 15 – 20 wt % of crystals; it is passed through a hydrocyclone and then a pusher centrifuge. Energy consumption, efficiency and economic optimization of the overall process were studied [221]; an energy flow diagram is given in [222].

Potassium chlorate is generally made from potassium chloride and sodium chlorate:

$$NaClO_3 + KCl \longrightarrow KClO_3 + NaCl$$

Solid KCl is added to the sodium chlorate cell liquor in stoichiometric amounts. The mixture is then transferred to a crystallizer and the potassium chlorate slurry is removed as described in the preceding paragraph. The mother liquor is recycled to the cells, where the salt is converted to chlorate and the process is repeated. Quality requirements for solid KCl are high, because no purification is possible after it is added to the solution.

7.5. Construction Materials

Chlorate solutions are kept slightly alkaline except during electrolysis, where a specific acidity must be maintained.

Mild steel and cast iron are suitable for equipment if the liquor is alkaline and free of active chlorine. In acidic media, poly(vinyl chloride) (PVC) tubes and tanks made from fiber-reinforced PVC are used up to 50 °C. Poly(vinyl chloride) stabilized with Ba or Cd (PVC-C) is much better suited, but the consumption rate is nevertheless 1 mm per year at 60 °C [223].

Titanium, polytetrafluoroethylene (PTFE), glass, and poly(vinylidene fluoride) (PVDF) have excellent resistance at all temperatures and under all conditions. Evaporators are made from yellow brass, rubber-lined steel, monel, stainless steel (AISI: 316; DIN: 1.4401) with cathodic protection, or titanium. Stainless steel should be used for the dryer because it is imperative to avoid Fe_2O_3 contamination of the chlorate, which would act as an explosion catalyst. Pump seals must be of the noncombustible type. Titanium is increasingly used in all equipment as the material for anodes, heat exchangers, reaction vessels, pumps, and tubes.

7.6. Environmental Protection

The gas released from the electrochemical reactor always contains some chlorine in addition to hydrogen and oxygen. The mixture passes a cooler, where the major amount of chlorine condenses. Residual amounts of chlorine (0.3 %) are lowered to $(1-3)\times10^{-4}$ % by absorption in alkaline solution (15 % NaOH) and to $(1-10)\times10^{-7}$ % by subsequent adsorption on activated carbon. The resulting gas mixture of hydrogen and some oxygen can either be vented to the atmosphere or used as a fuel. The oxygen concentration (1.5 – 2.5 %) depends on the reaction conditions of the cell (see Section 7.2). In trouble-free operation, environmental pollution problems do not arise. Pure hydrogen can be produced by passing the residual gas mixture over a noble metal catalyzing combustion and subsequently purified by selective permeation in palladium at elevated temperature (350 °C).

Wastewater from cleaning tanks and building floors requires appropriate treatment to avoid damage of the water flora by chlorates acting as herbicides. A process to remove almost 100 % of dichromate from chlorate solutions by use of a fixed bed of standard ion-exchange resin has been operated for several years in a pilot plant and is about to be commercially exploited [224].

7.7. Quality Specifications

The purity requirements of chlorate depend on the intended purpose and are usually negotiated between producer and user. Various products differ considerably in quality. Standard values for white and yellowish sodium chlorate and potassium chlorate are shown in Table 11. The given potassium chlorate quality is satifactory for many purposes, but may be recrystallized for special requirements (Table 11).

7.8. Storage, Transportation, and Safety

Chlorates should be stored in a cool, dry, fireproof building. Preferably, a separate storage building should be provided with cement floors and metal catwalks.

Wooden construction must be avoided because of the combustibility of chlorate-impregnated wood. Crystalline chlorate may be stored in concrete, lined steel bins, or glazed tile silos. Dried air should be supplied to prevent caking from atmospheric moisture. Drums and packages containing chlorates should not be stored where such noncompatible chemicals as acids, solvents, oils, organic substances, sulfur, or powdered metals could be spilled [225]. Ventilation must be provided for operations where fine chlorate dust arises. The ventilation system should discharge to a water scrubber and be designed for easy cleaning. Pumps handling chlorate solutions should be of the "packless" type. Electrical supply and distribution points are to be inspected periodically for dust. Motors and switches must not be housed in the plant or store and must conform to the National Electrical Code (United States). Metal or plastic pallets are recommended for handling containers.

Safety showers and water supply should be available to workers. The containers (barrels) must be kept closed and not be stored on top of each other. Chlorates are handled in polyethylene bags, in metal drums, or metal-lined fiberboard or plywood drums (25 – 170 kg). Bulk chlorates can be delivered by tank trucks or railroad tank cars either in the dry or wet state. They are usually unloaded as a slurry by recirculation of hot water (60 °C) between the car and the dissolver tank. The recommended material for storage tank construction is stainless steel (AISI

316). Tanks lined with rubber or plastics are not recommended because of possible fire or explosion hazards. For more details, see references [226–237].

7.9. Uses

Sodium Chlorate. The rapid growth of sodium chlorate production is mainly due to the widespread use of the chlorate-derived chlorine dioxide bleach by the pulp and paper industry. The once predominant use of sodium chlorate as a nonselective herbicide has strongly declined. Second in importance is its use as an intermediate in the production of other chlorates, mainly potassium chlorate, and of sodium perchlorate for conversion to ammonium perchlorate, which is used as an oxidizer in solid propellants. Sodium chlorate is further used as oxidizing agent in uranium refining and other metallurgical operations, as an additive to agricultural products and dyes, in textile and fur dyeing, metal etching, and in chemical laboratories and throughout the chemical industry as an oxidizing agent.

Potassium Chlorate. Potassium chlorate is used mainly in the manufacture of matches and in the pyrotechnics, explosives, cosmetics, and pharmaceutical industry; it is superior to sodium chlorate because of its smaller hygroscopicity.

Barium Chlorate. Barium chlorate is prepared by reaction of barium chloride with sodium chlorate solution. It is precipitated by cooling, purified by recrystallization, and used in pyrotechnics.

Calcium Chlorate. Solutions of calcium chlorate are used as herbicide.

7.10. Economic Aspects

Because of the steadily increasing demand for chlorine dioxide in the pulp industry, production of sodium chlorate has doubled in the past 10 years. Figure 19 shows annual production data. Canada is the world's leading producer with 0.5 Mt $NaClO_3$ in 1984, closely followed by the United States with 0.41 Mt $NaClO_3$.

Figure 19. Chlorate production capacities

Since electric power cost amounts to ca. one-third of the total production cost of sodium chlorate, cheap energy is the key economic factor.

8. Perchloric Acid and Perchlorates

Perchloric acid [*7601-90-3*] and its salts, particularly ammonium perchlorate [*7790-98-9*], NH_4ClO_4, sodium perchlorate [*7601-89-0*], $NaClO_4$, and potassium perchlorate [*7778-74-7*], $KClO_4$, find many applications because of their strong oxidizing power; their chemical stability is sufficient to permit high-energy oxidation under controlled conditions. Perchloric acid is used on a limited scale mainly as a reagent for analytical purposes; its production has increased because of its use as a starting material for pure ammonium perchlorate, a basic ingredient of explosives and solid propellants for rockets and missiles. Minor amounts of potassium perchlorate occur in Chile, in natural deposits of sodium nitrate.

Table 12. Density, ϱ, and vapor pressure, p, of anhydrous perchloric acid

	t, °C

p, kPa	1.546	2.506	3.913	4.826

8.1. Physical and Chemical Properties

8.1.1. Perchloric Acid

Anhydrous perchloric acid, M_r 100.5, can be obtained by distilling at reduced pressure a mixture containing 1 part of 20 % $HClO_4$ and 4 parts of 20 % oleum. It is a colorless, strongly hygroscopic liquid, melting at − 102 °C. At atmospheric pressure, it decomposes at 75 °C. Its density and vapor pressure vs. temperature are given in Table 12.

Perchloric acid is miscible with water in all ratios and forms a series of hydrates as shown in Table 13. Boiling points and densities vs. concentration are given in Table 14. For other physical properties, see [239], [240].

Anhydrous perchloric acid is a very strong oxidizing agent. Some metals like nickel, copper, silver, and gold are only slightly oxidized at ambient temperature. Platinum is not attacked, but it decomposes the acid by catalytic action. In contact with combustible materials, the perchloric acid reacts violently, forming explosive mixtures with paper, charcoal, ethanol, acetic anhydride, and gelatin.

Perchloric acid is more stable in aqueous solution than in anhydrous form. The azeotropic mixture (72.5 wt % $HClO_4$) decomposes in the absence of oxidizable matter only above the boiling point. Concentrated perchloric acid is a strong oxidizing agent, especially at high temperature; it forms explosive mixtures with organic compounds, which can detonate on heating, percussion, or exposure to sparks or a flame.

Perchloric acid is a strong acid and reacts in aqueous solution with metals, metal oxides, and hydroxides, as well as with salts of volatile acids, forming the corresponding perchlorates. Some oxides, e.g., CuO, catalyze the decomposition of perchloric acid. This occurs through a chain of reactions that give chlorine, oxygen, and water as ultimate products.

8.1.2. Perchlorates

At least one element in each group of the periodic table, except the noble gases, forms perchlorates; this includes not only metals, but also nonmetallic elements, such as nitrogen in hydrazine perchlorate [*13762-80-6*] or fluorine in fluorine perchlorate [*37366-48-6*]. Organic ammonium, diazonium, and sulfonium perchlorates form another large class. Perchlorates are generally colorless and well (or fairly) soluble in water and such organic solvents as alcohols, ketones, or esters. Table 15 lists the solubilities of some metal perchlorates. Other physical properties can be found in [227], [241], and [242].

When heated, alkali metal and alkaline-earth metal perchlorates decompose before reaching the melting point, with the exception of $LiClO_4$ (*mp* 247 °C). The hydrates of the perchlorates generally have definite melting points, but they decompose on further heating, after liberation of water.

The outstanding chemical property of the perchlorates is their strong oxidizing power. This is exploited either in mixtures of perchlorates with combustible materials or by using organic perchlorates as explosives or propellants. On the other hand, all perchlorates, also in the pure state, are liable to undergo explosive decomposition if they are heated above a critical temperature, with liberation of chlorides and oxygen; ammonium perchlorate has been investigated extensively in this respect in view of its importance for jet propulsion [243–248].

8.2. Production

8.2.1. Perchloric Acid

Perchloric acid is made from sodium perchlorate and hydrogen chloride [239], [249]. A saturated $NaClO_4$ solution reacts with an excess of HCl,

$Ca(ClO_4)_2$	188.60	$Ni(ClO_4)_2 \cdot 6\,H_2O$	267

and NaCl precipitates. The dilute per-chloric acid produced after filtration (32 % $HClO_4$) is concentrated in three stages up to 70 – 71 % $HClO_4$; the last stage is vacuum distillation.

A continuous, electrochemical process for the production of perchloric acid has been developed in the Federal Republic of Germany. It involves the anodic oxidation of gaseous chlorine dissolved in chilled 40 % $HClO_4$ [250], [251]:

$$Cl_2 + 8\,H_2O - 14\,e \longrightarrow 2\,HClO_4 + 14\,H^+$$

The electrolyzer is of the filter press type; it is composed of poly(vinyl chloride) (PVC) frames and the electrodes are separated by a diaphragm of PVC fabric. The anodes are made from platinum foil, spot-welded to tantalum rods. The cathodes are horizontally slitted silver plates. A 40 % $HClO_4$ solution is circulated from the electrolyzer to an external cooler, which keeps the temperature within − 5 to + 3 °C. The operating conditions are as follows: current 5000 A; current density 2.5 – 5 kA/m^2; voltage 4.4 V; current efficiency 0.60; and chlorine concentration at inlet 3 g/L. The outflowing solution is distilled to remove residual chlorine and byproduct hydrogen chloride and to obtain high-purity perchloric acid. Platinum consumption is 0.025 g/t of 70 % $HClO_4$; it dissolves at the anode, but partly redeposits at the cathode and can thus be recovered. Per ton of 70 % $HClO_4$, 9600 kWh of electricity (d.c.) is used. The high purity of the product, directly obtained by a continuous process not requiring separation stages, is an advantageous tradeoff versus the relatively low current efficiency. The process further allows unusual perchlorates to be prepared by direct conversion with perchloric acid, thus avoiding the route via sodium chlorate.

8.2.2. Perchlorates

Various methods for the production of perchlorates are described in [239]. In practice, commercial production is based on the following steps:

1) Electrochemical production of sodium chlorate from sodium chloride (Chap. 7)
2) Electrochemical oxidation of sodium chlorate in aqueous solution to sodium perchlorate
3) Conversion of sodium perchlorate into another perchlorate, e.g.:

$$NaClO_4 + KCl \longrightarrow KClO_4 + NaCl$$

$$NaClO_4 + NH_4Cl \longrightarrow NH_4ClO_4 + NaCl$$

In the last step, the corresponding sulfate, which causes fewer corrosion problems, can be used instead of the chloride.

This indirect method for the production of perchlorates other than $NaClO_4$ is advantageous over their direct electrosynthesis from the corresponding chlorates, because of their relatively small solubility in water (Table 15). Attempts have been made to make sodium perchlorate directly from sodium chloride, by a single electrolysis [252–254]. The advantage, however, seems debatable, because the resulting current efficiency is only slightly better than 50 % under optimum conditions.

Anodic Oxidation. The anodic oxidation of chlorate occurs according to the following overall reaction:

$$ClO_3^- + H_2O - 2e \longrightarrow ClO_4^- + 2H^+$$

The standard potential of the anodic process (1.19 V) is very close to that of water oxidation (1.228 V), which gives rise to oxygen evolution. Both reactions compete strongly, independent of the acidity of the solution. To obtain a satisfactory current efficiency, the anode potential should be as large as possible, because a high polarization enhances the chlorate oxidation rate more than the oxygen evolution [255]. This is achieved by selecting a suitable anode material and a high current density. Several reaction mechanisms have been proposed for chlorate oxidation to perchlorate [39].

Cell design and operating conditions must be selected to optimize electricity consumption, which depends on cell voltage and current efficiency. Both are affected by a number of variables in conflicting ways. In particular, the current efficiency is improved by increasing the current density, but this also increases the cell voltage. A temperature rise operates in reverse in that not only the voltage, but also the current efficiency is diminished. A high sodium chlorate concentration in the effluent liquor improves current efficiency as well as voltage, but requires more expensive procedures and higher chlorate consumption to obtain a sufficiently pure perchlorate solution.

Industrial Cells. Contrary to electrochemical chlorate production, the residence time of the electrolyte in the perchlorate cell is not a critical parameter. The cell is undivided and hydrogen gas evolution provides sufficient agitation to decrease the sodium chlorate concentration gradient between the cell inlet and outlet. Because of the relatively high heat dissipation, the cell is normally provided with internal cooling.

Smooth platinum anodes yield the highest oxygen overpotential and, hence, the highest current efficiency (95 – 97 %). Platinum is either used in foils or cladded onto rods of some other metal, such as tantalum or copper. Lead dioxide anodes are also used [256]; they consist of a lead dioxide deposit plated on some conductive substrate, such as graphite rods or plates [257–260]. They are less expensive than platinum, which more than offsets their lower current efficiency (85 %). When a small amount of sodium fluoride (2 g/L) is added to the electrolyte, the current efficiency increases [257]. More recently, platinate-coated titanium has been claimed to substitute profitably for massive smooth platinum in perchlorate manufacture [261].

Cathodes are made from carbon steel, chromium – nickel steel, nickel, or bronze. As in chlorate electrosynthesis, sodium dichromate is added to the solution to minimize the current efficiency loss caused by cathodic reduction of perchlorate. At the same time, dichromate inhibits corrosion of the steel parts that are directly exposed to the electrolyte, in addition to their cathodic protection. However, dichromate cannot be used with lead dioxide anodes, because it catalyzes oxygen evolution [255]. In that case, the most suitable cathode material is nickel or chromium – nickel steel.

Figure 20 shows some typical cell models [262]. In the *Bitterfeld* cell, each anode, made from platinum foil, works between a pair of cathodes made from perforated steel plates. The cell is kept at 35 °C by cooling water running through a steel pipe bundle.

In the *Cardox* cell, the anodes consist of platinum cladded onto copper rods 1.3 cm in diameter. Each anode is surrounded by a cathodic tube 7.6 cm in diameter, which is made from steel and perforated at both ends. This allows hydrogen gas to escape into the interelectrode space and ensures convective circulation.

Figure 20. Some typical models of perchlorate cells

Table 16. Typical operational data for perchlorate cells

Current	500 – 12 000 A
Current density	1500 – 5000 A/m^2
Cell potential	5 – 6.5 V
Current efficiency	
Platinum anodes	90 – 97 %
Lead dioxide anodes	85 %
Electric energy (d.c.)	
per ton of $NaClO_4$	2500 – 3000 kWh
Electrolyte temperature	35 – 50 °C
pH	6 – 10
Concentrations, g/L	
$Na_2Cr_2O_7$	0 – 5
Cell inlet	
$NaClO_3$	400 – 700
$NaClO_4$	0 – 100
Cell outlet	
$NaClO_3$	3 – 50
$NaClO_4$	800 – 1000
Platinum consumption per ton of $NaClO_4$	2 – 7 g

In the model of *American Potash and Chemicals* (formerly Western Electrochemical Co.), a set of anodic platinum foils is arranged around the inner wall of the cylindrical cell body performing as the cathode; the interelectrode gap is stabilized by a number of glass rod spacers. The temperature is kept at 40 – 45 °C by internal cooling and by a water jacket surrounding the cylindrical cell tank.

In the *Pechiney* model, the anodes are platinum foils and the cathodes are plates made from bronze.

Operation. Table 16 shows typical operational data [39], [239], [262]. Sodium perchlorate can be separated from the cell effluent either as hydrate or as anhydrous salt. Depending on concentration, separation is carried out by cooling alone or by evaporation, followed by cooling. The monohydrate precipitates from the solution below ca. 52 °C; above this temperature, the perchlorate crystallizes as the anhydrous salt. In either case, the mother liquor still contains a large amount of perchlorate. After enrichment

with sodium chlorate, this solution is recycled to the electrolysis process.

When the sodium perchlorate is used for conversion to other perchlorates, it need not be separated from the cell effluent. Sodium chlorate is destroyed by chemical treatment and dichromate precipitated as insoluble chromic hydroxide. The purified and concentrated solution is then ready for conversion to other salts [263].

8.3. Environmental Protection

On account of the limited volume produced and their slight toxicity, perchlorates do not constitute an environmental pollution problem. Aquatic life (fish, leeches, and tadpoles) survives indefinitely even when the perchlorate concentration in water exceeds 500 mg/L [264]. However, because of the antithyroid effect of perchlorate, some chronic symptoms may appear at low levels.

Some bacteria, such as *Vibrio dechloraticans,* can metabolize perchlorates; this is exploited for perchlorate destruction in the sanitation of contaminated sewage waters.

8.4. Chemical Analysis

Perchlorate is analyzed by its decomposition to chloride. This occurs by melting the perchlorate salt in a platinum dish with sodium carbonate, which accelerates the thermal decomposition. Sodium carbonate can be replaced with ammonium chloride if alkali-metal perchlorates are analyzed that decompose rapidly at 450 – 550 °C. The cooled melt is then dissolved in water or dilute nitric acid, and the total chloride is determined by normal volumetric or gravimetric methods. The chlorate or chloride content initially present in the sample must be subtracted to obtain the amount of perchlorate in the sample.

Quantitative precipitation of perchlorate from an aqueous solution by one of the following reagents is also possible: methylene blue [265]; potassium, rubidium, or cesium salts in cold ethanol – water solution [266]; or tetraphenylphosphonium chloride [267], [268]. The most sensitive quantitative determination of perchlorate ($10^{-6} - 10^{-7}$) is possible by means of ion-specific electrodes [269], [270].

8.5. Storage, Transportation, and Safety

The same storage and shipping regulations that apply to chlorates (Section 7.8) are also applicable to perchlorates.

According to the U.S. Department of Transportation (DOT) regulations for hazardous materials, perchloric acid and perchlorates are shipped in glass containers or metal drums as specified in [271]. They are classified as oxidizing substances and require oxidizer shipping labels. Transportation is forbidden on passenger-carrying aircraft or railcars. Shipment of perchloric acid in concentrations greater than 72 % is forbidden. Ammonium perchlorate may be shipped in steel drums with plastic liners; large quantities are transported in portable aluminum containers holding up to 2.27 t. Lower-side or hopper-type product discharge openings are not permitted.

Sodium or magnesium perchlorate may be shipped wet in tank cars with a minimum of 10 % water, which must be equally distributed. All perchlorates not specifically covered by DOT regulations should carry special precautionary labels indicating the specific fire or explosion hazards expected from the individual perchlorate.

Despite their limited toxicity, perchloric acid and perchlorates must be considered, like chlorates, as hazardous chemicals during fabrication, transportation, and handling. Because of its tendency toward spontaneous explosion, anhydrous perchloric acid should be prepared only in very small batches and in the absolute absence of impurities. It can be stored for a limited time at low temperature and must be protected from any kind of contamination. Distillation must be carried out under vacuum (2.4 kPa at 16 °C) and with protective shielding. One must never try to obtain the acid in anhydrous form by treatment with a drying agent. It should be stored in glass containers with glass stoppers, possibly embedded in kieselguhr or glass wool for protection.

Ammonium perchlorate and alkali-metal and alkaline-earth metal perchlorates are relatively insensitive to rubbing, heating, and shock. They also require special precautions in manufacturing and further handling [225], [226]. Clean work clothing must be worn each day and laundered afterward; it must not be taken home.

Clothing wet with perchlorate solution should be changed before drying. No smoking can be permitted in perchlorate working areas or while wearing work clothes. Deluge type safety showers or jump tanks should be provided. Only rubber shoes and rubber or rubberized gloves are permitted.

Perchlorates should not be stored close to flammable materials, reducing agents, or other hazardous substances. Buildings in working areas should be fireproof. Dust control or dust prevention in perchlorate solutions is particularly important. Since mixtures of such solutions with oil or grease are violently explosive, motor and pump bearings must be provided with special lubricating and washing devices [225]. Fires must be extinguished with water, but carbon dioxide may provide sufficient cooling to extinguish small fires. Dry powder is ineffective because it cannot smother a self-sustaining fire. For burns, cold water treatment should be used as quickly as possible. For other first aid measures, consult [226].

A second class of more hazardous compounds is formed by inorganic perchlorates containing nitrogen or heavy metals, organic perchlorates, or mixtures of inorganic perchlorates with organic substances, finely divided metals, or sulfur. They are all very sensitive to rubbing, shock, percussion, sparks, and heating and must, therefore, be handled with the same precautions as high explosives (→ Explosives).

8.6. Uses

Perchloric Acid. The commercial product is the azeotropic, aqueous solution of 72.5 % $HClO_4$ (*bp* 203 °C). In analytical chemistry, it serves to determine the metallic elements present in oxidizable substances, such as organic compounds [272–277]. Perchloric acid is an acetylation catalyst for cellulose and glucose and is used in the preparation of cellulose fibers.

Perchlorates. The most outstanding property of ammonium perchlorate is its high oxygen concentration (54.5 % O_2) and the fact that it decomposes without leaving a solid residue. Therefore, it is used as an oxidizing component in solid rocket propellants.

Lithium perchlorate is used in lithium–nickel sulfide dry batteries [278], and sodium perchlorate in electrochemical machining [279]; potassium perchlorate is a component of pyrotechnics and an ignition ingredient in flash bulbs [280]. Magnesium perchlorate is known as a very effective drying agent.

Ammonium perchlorate mixed with an epoxy resin forms a temporary adhesive between two metallic surfaces, such as two steel plates. These can be separated whenever desired by heating at ca. 300 °C because of the self-sustained combustion of the adhesive layer [281]. Ammonium perchlorate has been tried as a feed supplement to increase the weight of livestock, with an optimum dose of 2 – 5 mg/kg [282–286]. Perchlorates have also proven to be helpful in oxygen-regenerating systems to be used in enclosed environments, such as submarines and spacecraft, and in breathing equipment [287]. Potassium values from enriched bittern, obtained from the Dead Sea or the Great Salt Lake, can be recovered by precipitating potassium perchlorate with sodium perchlorate [288], [289].

8.7. Economic Aspects

Statistical data about the production and use of perchlorates are not easily accessible because of their strategic importance. The United States' production in 1974 was reported to be ca. 25 000 t, or ca. 12 % of the chlorate production [290]. On account of the increasing developments of artificial satellites and space shuttle programs, perchlorate production will increase, due to their major use in solid propellants.

9. Toxicology and Occupational Health

Hypochlorous acid and hypochlorites are toxic because they liberate chlorine on contact with acid. Sodium hypochlorite solution produced by on-site electrolyzers (available chlorine concentration 0.5 – 10 g/L) is regarded as corrosive and as an irritant when ingested or inhaled. It is also a mild skin irritant, and prolonged exposure may result in a burn or rash [56]. However, concentrated hypochlorous acid burns human skin in seconds.

Chlorine Dioxide. Chlorine dioxide gas is the most toxic and hazardous of all chlorine oxides. Even when small amounts of chlorine dioxide are inhaled, the respiratory system is severely damaged [291]. The symptoms of chlorine dioxide intoxication depend on its concentration and on the exposure time; they include lacrimation, headache, vomiting, severe cough, asthmatic bronchitis, dyspnea, and even death. Such defects as dyspnea or asthmatic bronchitis only heal slowly after the exposure to chlorine dioxide has ceased.

Exposure to 5 ppm of chlorine dioxide in air during several hours severely irritates the mucous membranes [292]; short-term exposure to 20 ppm may cause death. According to animal experiments and observations of employees in chlorine dioxide production plants, the human and animal organisms are extremely sensitive to chlorine dioxide, in particular when the concentrations are higher than 1 ppm [291–294].

Chlorine dioxide levels below 0.1 ppm are relatively harmless [295], [296]. Exposure of rats to 0.1 ppm of chlorine dioxide (5 h/d; 10 weeks) showed no toxic effects whereas repeated inhalation of 10 ppm of chlorine dioxide caused death.

The odor threshold of chlorine dioxide is less than 0.1 ppm [297], [298]. The MAK and the TLV of chlorine dioxide have been established at 0.1 ppm (0.3 mg/m^3).

Chlorine dioxide production plants must be operated at slightly subatmospheric pressure. The plant design must also account for the high explosiveness of chlorine dioxide; therefore, chlorine dioxide is diluted with air to below 15 % before it leaves the generator. No attempt should ever be made to transport chlorine dioxide over long distances in any form.

Chlorates. The major health hazard of the chlorates arises from their extreme danger of flammability on contact with oxidizable substances. Irritation of the skin, mucous membranes, and eyes may occur from prolonged exposure to dusty atmospheres. Contrary to chlorides, the chlorates are strong blood toxins. Chlorates are readily absorbed by the mucous membranes; doses of a few grams of chlorate are lethal for humans. Abdominal pain, nausea and vomiting, diarrhea, pallor, blueness, shortness of breath, and unconsciousness are the immediate symptoms when toxic amounts of chlorates are ingested. In workplaces with dust formation, dust masks must be worn. Cases of chronic toxicity have not been reported. The instructions for industrial safety must carefully be observed [226], [227], [229]. For detailed information on precautionary and first aid procedures, see [228], [233–237].

Perchlorates. Sodium perchlorate appears in the urine of humans within 10 min after ingestion and is largely eliminated within 5 h. During many years of large-scale production of alkali-metal perchlorates, no case of perchlorate intoxication has been reported [239]. Industrial experience also indicates that these salts are not particularly irritating to the skin or mucous membranes, although inhalation should be avoided. A sodium perchlorate dose of 2 – 4 g/kg is lethal to rabbits.

1. Introduction

Chloroacetaldehydes are described by the general formula $CH_{3-x}Cl_xCH{=}O$ (x = 1, 2, 3). Chloroacetaldehydes are colorless liquids which form solid hydrates with water. The stability of the hydrates increases with the increasing number of chlorine atoms due to changed reactivity of the aldehyde group. Whereas monochloroacetaldehyde undergoes typical aldehyde reactions, the aldehyde group of trichloroacetaldehyde forms addition compounds with nucleophilic reagents.

Chloroacetaldehydes became important in organic synthetic chemistry. Today mainly monochloroacetaldehyde is of commercial and industrial importance as intermediate in the synthesis of pharmaceuticals, agrochemicals, and fragrances.

Chloroacetaldehydes are used as pure substances, hydrates, or aqueous solutions. Monochloroacetaldehyde is mainly used as an aqueous solution because isolation of pure

monochloroacetaldehyde is expensive and an aqueous solution is suitable for most reactions.

2. Monochloroacetaldehyde

Monochloroacetaldehyde [*107-20-0*], 2-chloroethanal, CH_2ClCHO, M_r 78.50, was first prepared in pure form by K. Natterer in 1882 by heating chloroacetaldehyde diethyl acetal, $CH_2ClCH(OC_2H_5)_2$ [*621-62-5*], with anhydrous oxalic acid at 100–150 °C. Monochloroacetaldehyde was obtained from the aqueous solution as a crystalline hemihydrate.

2.1. Physical Properties

Anhydrous monochloroacetaldehyde is a colorless, mobile liquid with extremely pungent odor; *bp* 85–85.5 °C (99.7 kPa), enthalpy of formation of the liquid from the elements −256.4 kJ/mol, enthalpy of combustion −981.4 kJ/mol (at 101.3 kPa, 20 °C), dipole moment 1.99 D (at 298 K in benzene). It is soluble in water (to form a hydrate) and in common organic solvents. The octanol–water partition coefficient of the substance is very low (0.16).

Monochloroacetaldehyde hemihydrate 1,1′-dihydroxy-2,2′-dichlorodiethyl ether, 1,1′-oxybis-(2-chloroethanol), $CH_2ClCH(OH)-O-CH(OH)CH_2Cl$, M_r175.01, colorless crystals, *mp* 43–50 °C (elimination of water), *bp* (with decomposition into the components) 84 °C, is soluble in water (see Tables 1 and 2), ethanol, ether, benzene, methylene chloride, and chloroform.

Two CAS numbers, [*34789-09-8*] and [*7737-02-2*], are given for chloroacetaldehyde hemihydrate. The first is valid for the term "acetaldehyde, chloro dimer, hydrate" and the second for "1,1′-oxybis(2-chloroethanol)." These compounds are identical.

The hemihydrate distills from the aqueous solution as an azeotropic mixture. Both components, chloroacetaldehyde and water, are present in the vapor phase, but they cannot be separated by a simple distillation. Figure 1 shows the composition of the vapor and the liquid of a monochloroacetaldehyde–water mixture, and Figure 2 shows the boiling and condensation points as functions of the composition.

Figure 1. Vapor–liquid equilibrium curve for monochloroacetaldehyde–water [1]

Figure 2. Boiling and condensation curve of aqueous chloroacetaldehyde solutions [1]

Safety Data (for the hemihydrate):

Flash point 60 °C
Ignition point 405 °C [2]
Explosive limits in air (at 20 °C, 101.3 kPa), lower 305 g/m^3
MAK (Germany) deferred; substantial suspicion of a carcinogenic potential, Cat. 3; H (skin absorptive) [3]
MAK (Germany): annulled [4]
TLV-STEL (USA): 1 ppm [5]

For chloroacetaldehyde NIOSH has defined an immediately dangerous to life or health concentration (IDLH) of 45 ppm based on acute inhalation toxicity data in humans [6].

Table 1. Solubility of monochloroacetaldehyde hemihydrate in water as a function of temperature [1]

Temperature, °C	1	10	20	30	40
Concentration, wt %	13.35	22.2	44.3	62.7	81.5

Table 2. Density of aqueous chloroacetaldehyde hemihydrate solutions at 15 °C as a function of concentration [1]

Concentration, wt %	10	20	30	40	50	60	72.5
Density, g/cm^3	1.041	1.085	1.137	1.188	1.238	1.290	1.355

2.2. Chemical Properties and Uses

Like other α-halocarbonyl compounds, chloroacetaldehyde is exceptionally reactive. The aldehyde group takes part in reactions typical of this group, e.g., addition and condensation. Other reactions involve the chloromethyl group. Nucleophilic substitution of the chlorine is facilitated by the inductive effect of the aldehyde group. The α-hydrogens atoms are likewise strongly activated by the inductive effects of the aldehyde group and the chlorine atom.

2.2.1. Reactions of the Aldehyde Group

Like acetaldehyde, anhydrous chloroacetaldehyde self-condenses easily at room temperature to form a cyclic trimer and tetramer as well as polymers with an acetal (polyoxymethylene) structure. Cotrimers and copolymers with acetaldehyde are also known. The hemihydrate has the structure 1,1′-dihydroxy-2,2′-dichlorodiethyl ether, $ClCH_2CH(OH)-O-CH(OH)CH_2Cl$, and reacts like an aldehyde.

Among industrially important derivatives are the crystalline sodium bisulfite addition compound, sodium 2-chloro-1-hydroxyethanesulfonate [*13064-50-1*], the dimethyl acetal [*97-97-2*] (*bp* 127–128 °C), and the diethyl acetal [*621-62-5*] (*bp* 157.4 °C), which are used in preparing pharmaceutical precursors and pesticides.

Oxidation with air in the presence of cobalt salts [7], hydrogen peroxide, nitric acid [8], or other oxidants yields monochloroacetic acid. Aldol addition in an alkaline medium gives 2,4-dichloroacetaldol, which can be dehydrated to 2,4-dichlorocrotonaldehyde in an acid medium. In coaldolization with acetaldehyde, chloroacetaldehyde reacts exclusively as the methylene component to produce 2-chlorocrotonaldehyde. This aldehyde is also obtained as a byproduct of acetaldehyde production (→ Acetaldehyde).

Other typical aldehyde reactions are the formation of the aldehyde ammonia, 1,3,5-tris-(chloromethyl)hexahydro-2,4,6-triazine [*7038-17-7*] [9], the cyanohydrin [*33965-80-9*], $ClCH_2CH(OH)CN$ [10, 11], and 2-chloroethyl chloroacetate, $ClCH_2COOCH_2CH_2Cl$ [*3848-12-2*], (Tishchenko reaction) [9].

2.2.2. Reactions at the Chlorine Atom

The chlorine atom can be removed by hydrogenation using a palladium–carbon catalyst in aqueous solution [12], and can be replaced by nucleophilic agents [13].

Mercaptoacetaldehyde is formed by the reaction of chloroacetaldehyde with sodium mercaptan. It is used as an intermediate in the synthesis of thienodiazepines, a new class of tranquilizers [14, 15], of thiophenic azo dyes, of *d,l*-cystein, and of certain 2-alkylthiazoline food flavors [16]. Mercaptoacetaldehyde exists as an equilibrium mixture of the dimer, 2,5-dihydroxy-1,4-dithian [*40018-26-6*] [17], and oligomers [18].

Substitution of the chlorine atom by the amino or methylamino groups is carried out on the acetal to protect the aldehyde group. The amino and methylamino derivatives are intermediates in the synthesis of pesticides and pharmaceuticals [19].

Reaction of chloroacetaldehyde dimethyl acetal with sodium methoxide yields 1,1,2-trimethoxyethane, which is also an intermediate in pharmaceutical syntheses, e.g., sulfamethoxydiazine.

2.2.3. Reactions of the Chlorine and Aldehyde Groups

Chloroacetaldehyde, usually in form of the hemihydrate or an acetal, is used as a starting compound for preparing numerous heterocyclic

compounds. The most industrially important reaction is the synthesis of 2-aminothiazole by reaction with thiourea.

2-Aminothiazole is an intermediate in the preparation of pharmaceuticals, e.g., sulfathiazole, and dyes. Cyclocondensation of chloroacetaldehyde with methyl acetoacetate gives 2-methyl-3-carbomethoxyfuran, an intermediate in making the seed disinfectant fenfuram [20]. 5-Chlorothiadiazole, an intermediate for the cotton defoliant and plant growth regulator thidiazuron, is obtained by condensation of chloroacetaldehyde with carboethoxyhydrazine and subsequent cyclization with thionyl chloride [21].

Stilbenes are produced by the reaction of chloroacetaldehyde with aromatic hydrocarbons, phenols, or phenol ethers [22]. Vinyl dialkyl phosphates are produced by reaction with trialkyl phosphites (Perkow reaction) [23]. Reaction with sodium acetate and acetic anhydride forms 1,1,2-triacetoxyethane, which can be used as a starting material for producing *d,l*-serine [24].

2.2.4. Uses of Chloroacetaldehyde

Chloroacetaldehyde finds application in the manufacture of pharmaceuticals, e.g., as starting material to synthesize statine intermediates. The mercapto derivative of chloroacetaldehyde, 2,5-dihydroxy-1,4-dithiane, is an important building block for drugs against AIDS [25]. Besides its application in the synthesis of pharmaceuticals, chloroacetaldehyde is used as a raw material to make dyestuffs. Dialkylacetal derivatives of chloroacetaldehyde such as chloroacetaldehyde dimethyl acetal are important starting materials for the manufacture of agrochemicals. The acetals are also used to make fragrances.

2.3. Production

2.3.1. Chlorination of Acetaldehyde and Paraldehyde

Chlorination of acetaldehyde or paraldehyde yields monochloroacetaldehyde mixed with small amounts of dichloroacetaldehyde and trichloroacetaldehyde. These three compounds are also obtained as byproducts of the production of acetaldehyde by the Wacker process (→ Acetaldehyde).

2.3.2. Chlorination of Vinyl Compounds in Aqueous Media and Alcohols

Simultaneous introduction of vinyl chloride and chlorine into water at ca. 20 °C forms chloroacetaldehyde in a nearly quantitative yield if its concentration in the reaction solution is not allowed to rise above ca. 5 wt %. At a higher concentration, increasing amounts of 1,1,2-trichloroethane are formed [26].

$$CH_2 = CHCl + aHOCl \rightarrow [ClCH_2CH(OH)Cl] \rightarrow ClCH_2CHO + HCl$$

This method yields only a dilute solution of chloroacetaldehyde. Concentrated aqueous solutions of chloroacetaldehyde are obtained in nearly quantitative yields by the reaction of chlorine with vinyl acetate in water at room temperature [27 – 29]. As an intermediate 1,2-dichloroethyl acetate is formed, which is quantitatively hydrolyzed at elevated temperatures.

$$CH_2 = CHOOCCH_3 + Cl_2 \longrightarrow ClCH_2CHClOOCCH_3 \xrightarrow{H_2O} ClCH_2CHO + HCl + CH_3COOH$$

The resulting solution is purified by distillation. Side products are only small amounts of higher chlorinated acetaldehydes, acetaldehyde, and condensation products.

Chloroacetaldehyde acetals are obtained in high yield and purity by carrying out the above reactions in alcohols [30, 31].

2.3.3. Preparation of Anhydrous Chloroacetaldehyde

Direct chlorination of dry acetaldehyde or paraldehyde gives only a low yield of monochloroacetaldehyde. Azeotropic dehydration of the hemihydrate with chloroform, toluene [32], or carbon tetrachloride [33] followed by distillation over anhydrous calcium chloride gives better yields. Anhydrous monochloroacetaldehyde is obtained in high yield by the depolymerization of trichloroparaldehyde or polychloroacetaldehyde at 145 °C in the presence of oxalic acid or

trichloroacetic acid [34]. Monochloroacetaldehyde is also obtained in high yield by pyrolysis of chloroethylene carbonate in the presence of quaternary ammonium salts [35, 36].

2.4. Analysis

Chloroacetaldehyde is commercially available as a 45 wt % aqueous solution. The monochloroacetaldehyde content can be determined by reaction with excess hydrazine sulfate to form chloride ion, which can be determined by the Volhard method. Due to side reactions and reaction with other aldehydes this method is not very specific to monochloroacetaldehyde. The monochloroacetaldehyde content of an aqueous solution can be determined by density and side products by GC [37].

The usual aldehyde reactions are suitable for identification purposes. Monochloroacetaldehyde forms derivatives with characteristic boiling or melting points: oxime, *bp* 61 °C at 2.7 kPa; semicarbazone, *mp* 146–148 °C; thiosemicarbazone, *mp* 141–142 °C; 2,4-dinitrophenylhydrazone, *mp* 154–156 °C; 2,4,6-trinitrophenylhydrazone, *mp* 159–160 °C (crystallized from glacial acetic acid).

Gas chromatography can separate and determine chloroacetaldehyde and its impurities [13]. Due to formation of hydrates this method is not specific to the content of chloroacetaldehyde.

2.5. Transportation, Storage, and Safety

2.5.1. Transportation

A 45 % aqueous chloroacetaldehyde solution can be shipped or stored in glass, enamel, enamelled steel, and phenolic-resin-coated steel containers. Stainless steel and polyethylene are other suitable materials for transporting the product and for storing it, but only for a short time.

Transportation of chloroacetaldehyde is regulated (UN 2232 class 6.1, I; IACO/IATA: forbidden).

2.5.2. Storage

Aqueous 45 % chloroacetaldehyde should be stored in an inert atmosphere, and it remains in good condition for at least 3 months if kept in the dark at room temperature. If it is exposed to sunlight or allowed to become warm, it discolors, and eventually brown, resinous products form with the liberation of hydrogen chloride. If the solution is kept at temperatures below 15 °C, the hemihydrate may crystallize out.

2.5.3. Safety

Chloroacetaldehyde solutions must not be heated. At elevated temperatures a strong exothermic condensation may occur. Tightly fitting goggles and gloves made of butyl or nitrile rubber or coated with neoprene (wear gloves for short periods only, < 10 min) should be worn when chloroacetaldehyde is handled because of its strongly irritating effect. The compound should not be allowed to come in contact with the skin, eyes, or clothes, and its vapors should not be inhaled. Adequate ventilation should be provided. Areas in which chloroacetaldehyde is being handled should be provided with a safety shower or comparable means of quickly washing the skin.

A gas mask fitted with filter ABEK should be worn if there is a risk of inhaling the vapor. In case of long or strong exposure a positive-pressure self-contained breathing apparatus is necessary. In the event of a spill, all potential sources of ignition must be kept far away. Use of personal protection equipment is necessary. The spill should be mopped up with an absorbent substance, such as sawdust, fine sand, or silica granules. Emission of the substance into surface waters, drains or sewers, and open soil must be prevented due to the toxic effects on aquatic organisms and inhibiting effects on bacteria. Disposal of chloroacetaldehyde can be effected by treating a dilute water solution with alkali at elevated temperature followed by biological treatment or incineration, always in compliance with local regulations.

Because of its high biocidal activity, chloroacetaldehyde interferes with the biological degradation of organic substances in wastewater treatment plants. Alkali treatment at elevated temperature converts it into nontoxic biodegradable compounds by eliminating chlorine.

2.6. Polymeric Chloroacetaldehydes

Trichloroparaldehyde [1129-52-8] 2,4,6-tris (chloromethyl)-1,3,5-trioxane, $C_6H_9Cl_3O_3$, M_r 235.50, *mp* 88–89 °C, *bp* 140–144 °C (1.3 kPa), colorless crystals, soluble in common organic solvents, can be recrystallized from ethanol and forms monochloroacetaldehyde on heating in the presence of acids, e.g., oxalic acid.

Trichloroparaldehyde is formed by the reaction of concentrated sulfuric acid with the hemihydrate of monochloroacetaldehyde [38] and is also part of the residue (with tetrachlorometaldehyde) left by azeotropic distillation of the hemihydrate [9]. Trichloroparaldehyde can also be obtained by decomposing 1,2-dichloroethyl nitrate in the presence of Lewis acids, such as tin tetrachloride [39].

Tetrachlorometaldehyde [7038-25-7] 2,4,6,8-tetrakis(chloromethyl)-1,3,5,7-tetroxocane, $C_8H_{12}Cl_4O_4$, M_r 313.99, is obtained as a residue following azeotropic dehydration of chloroacetaldehyde hemihydrate [9]. It forms colorless crystals, *mp* 65–67 °C, *bp* 127–130 °C at 1.3 Pa.

Polychloroacetaldehydes [27577-42-0], $(C_2H_3ClO)_x$, are formed by the polymerization of anhydrous monochloroacetaldehyde at −40 to −78 °C, particularly in the presence of such Lewis acids as boron trifluoride in ether or chloroform, to form amorphous, elastomeric products with a polyacetal (polyoxymethylene) structure [40, 41].

Crystalline polymers are obtained at −78 °C in the presence of catalytic amounts of organometallic compounds, such as triethylaluminum, diethylzinc, or butyllithium [42].

Polymeric chloroacetaldehydes are commercially unimportant.

3. Dichloroacetaldehyde

Dichloroacetaldehyde [*79-02-7*], 2,2-dichloroethanal, $CHCl_2CHO$, M_r112.94, was first obtained in 1868 by F. Paterno by distillation of dichlorodiethyl acetal [*619-33-0*], $CHCl_2CH(OC_2H_5)_2$, with sulfuric acid.

3.1. Physical Properties

Anhydrous dichloroacetaldehyde is a colorless liquid with a strong odor, *mp* −37.6 to −37.4 °C, *bp* 89.2 °C, d_{25} 1.4113, dipole moment 2.36 D at 30 °C, soluble in water with formation of a hydrate and in common organic solvents.

Dichloroacetaldehyde monohydrate [16086-14-9], $CHCl_2CH(OH)_2$, 2,2-dichloro-1,1-ethanediol, crystallizes from water, M_r 130.96, *mp* 35–50 °C, *bp* 85–95 °C at 101.3 kPa, d_4^{20} 1.53–1.54, vapor pressure ca. 6.5 kPa at 20 °C and ca. 25 kPa at 50 °C, soluble in polar organic solvents, insoluble in nonpolar organic solvents. The flash point is ca. 95 °C and the ignition temperature ca. 605 °C.

3.2. Chemical Properties and Uses

On standing, dichloroacetaldehyde forms a solid, colorless polymer which depolymerizes if heated to 120 °C [43]. Dichloroacetaldehyde shows all of the typical aldehyde reactions.

Oxidation of dichloroacetaldehyde with chromic acid yields dichloroacetic acid [44]. Reduction with ethylaluminum gives 2,2-dichloroethanol [45]. Aldol condensation yields 2,2,4,4-tetrachloroacetaldol [46].

Condensation with ethylbenzene yields *p,p′*-diethyl-1,1-diphenyl-2,2-dichloroethane [*72-56-0*], which is known as Perthane and is used as an insecticide. Condensation with chlorobenzene produces *p,p′*-dichloro-1,1-diphenyl-2,2-dichloroethane [*72-54-8*], which is also an insecticide and is known as TDE or DDD.

$$CHCl_2CHO + 2C_6H_5Cl \rightarrow CHCl_2CH(C_6H_4Cl)_2 + H_2O$$

The most important use for dichloroacetaldehyde and its acetals is in the synthesis of the diuretic trichloromethiazid and the cytostatic mitotane [*53-19-0*],1,1-dichloro-2-(*o*-chlorophenyl)-2-(*p*-chlorophenyl)ethane.

3.3. Production

The most important industrial production process is the chlorination of acetaldehyde or paraldehyde. Hypochlorination of 1,2-dichloroethylene yields pure dichloroacetaldehyde.

3.3.1. Chlorination of Acetaldehyde or Paraldehyde

Dichloroacetaldehyde is formed, along with mono- and trichloroacetaldehyde, by the chlorination of acetaldehyde or paraldehyde [47]. High yields are obtained in the presence of antimony trichloride (83 % yield) [48] or phosphoric acid (> 90 % yield) [49].

Dichloroacetaldehyde is also formed, together with mono- and trichloroacetaldehyde, by oxychlorination in the preparation of acetaldehyde by the Wacker process (→ Acetaldehyde).

3.3.2. Hypochlorination of 1,2-Dichloroethylene

Dichloroacetaldehyde is obtained without impurities such as chloral and monochloroacetaldehyde, by treating 1,2-dichloroethylene with 1 mol of chlorine at 0–20 °C in aqueous dioxane [50] or in water alone with vigorous mixing [51].

3.3.3. Chlorination of Ethanol

Chlorination of ethanol can be controlled in the presence of nickel(II) chloride to obtain principally dichloroacetaldehyde along with some chloral and monochloroacetaldehyde. Dichloroacetaldehyde forms a hemiacetal, which can be used in the same manner as the pure aldehyde or the hydrate [52].

3.4. Availability, Storage, and Transportation

Dichloroacetaldehyde is available in a polyethylene container either as the solid hydrate (minimum 82 % anhydrous product) or as an aqueous solution (minimum 65 % anhydrous product).

3.5. Polymeric Dichloroacetaldehydes

Hexachloroparaldehyde [17352-16-8,] 2,4,6-tris(dichloromethyl)-1,3,5-trioxane, $C_6H_6Cl_6O_3$, M_r 338.83, *mp* 131–132 °C, colorless crystals, *bp* 210–220 °C with the formation of small amounts of dichloroacetaldehyde.

Hexachloroparaldehyde is made by treating dichloroacetaldehyde with such Lewis acids as antimony trichloride, iron(III) chloride, aluminum trichloride, tin(IV) chloride, or boron trifluoride [53]. Hexachloroparaldehyde is also formed by the direct chlorination of paraldehyde with 6–7 mol of chlorine at 35 °C under anhydrous conditions. It forms dichloroacetaldehyde hydrate in the presence of aqueous acids [54].

Polydichloroacetaldehydes [28388-44-5] , $(C_2H_2Cl_2O)_x$, are formed by polymerization of dichloroacetaldehyde. Crystalline polymers are obtained by treating dichloroacetaldehyde at −78 °C with organometallic compounds such as triethylaluminum, diethylzinc, or butyllithium [42]. Amorphous polymers are obtained by using Lewis acids at a temperature below 0 °C [55]. These products have a polyoxymethylene (polyacetal) structure and are more or less soluble in common organic solvents, depending on the degree of polymerization. They dissolve in concentrated sulfuric acid at 100 °C with discoloration, are soluble in dimethylformamide, and form copolymers with other aldehydes.

4. Trichloroacetaldehyde

Trichloroacetaldehyde[*75-87-6*], chloral, 2,2,2-trichloroethanal, CCl_3CHO, M_r 147.39, was first synthesized by J. von Liebig in 1832 by chlorination of ethanol. It was the first hypnotic drug (1869) and is a precursor of the famous insecticide DDT, 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane [*50-29-3*], discovered in 1941. Chloral was an important chemical in the 1960s, but its importance has steadily declined since then because the use of DDT and other chlorinated insecticides has been restricted.

4.1. Physical Properties

Chloral, *mp* −56.5 °C, *bp* 97.8 °C at 101.3 kPa, d_4^{20} 1.5121, n_D^{20} 1.4557, vapor pressure 4.7 kPa at 20 °C, is a colorless, mobile, oily liquid.

It has a penetrating odor and is readily soluble in water, alcohol, ether, and chloroform. The octanol–water partition coefficient is low (0.99). It forms azeotropes with 1,2-dichloroethane, heptane, and benzene.

4.2. Chemical Properties

The strong electron-withdrawing effect of its three chlorine atoms gives chloral chemical properties different from those of most aldehydes [56]. It has a strong tendency to form addition compounds with nucleophilic reagents. For example, with alcohols (ROH, R = alkyl) it forms isolable hemiacetals, $CCl_3CH(OH)OR$, and with water isolable chloral hydrate, $CCl_3CH(OH)_2$ [*302-17-0*], *mp* 53 °C; *bp* 97.5 °C at 101.3 kPa; d_4^{20} 1.908. Chloral cannot undergo many of the base-catalyzed condensations typical of aldehydes because strongly basic reagents tend to cleave its carbon–carbon bond.

$$CCl_3CHO + NaOH \rightarrow CHCl_3 + HCO_2Na$$
$$CCl_3CHO + R_2NH \rightarrow CHCl_3 + HCONR_2 \quad (R = \text{alkyl})$$

Under acidic conditions chloral usually reacts as a typical aldehyde, forming acetals with alcohols and condensing with aromatic compounds to form diaryltrichloroethanes, e.g., DDT from chlorobenzene.

$$CCl_3CHO + 2\,C_6H_5Cl \xrightarrow{H_2SO_4} CCl_3CH(C_6H_4Cl\text{-}p)_2 + H_2O$$

Anionic initiators such as lithium *tert*-butoxide convert chloral to an insoluble, nonflammable high polymer, $[CH(CCl_3)O]_n$, that has not found commercial use [57].

4.3. Production

Chloral is produced by the chlorination of acetaldehyde [58] (→ Acetaldehyde) or ethanol (→ Ethanol). Acetaldehyde is usually the more economical starting material.

$$CH_3CHO + 3Cl_2 \rightarrow CCl_3CHO + 3HCl$$

The chlorination is carried out in hydrochloric acid, which speeds up the reaction, represses condensation and aldehyde-oxidation reactions, and facilitates temperature control. Antimony trichloride is sometimes used as a catalyst. The process can be performed either in batches or continuously. The rate of chlorination decreases as the stepwise chlorination proceeds; thus, the temperature is gradually increased from 0 °C to 90 °C during the process. Chloral is distilled from the reaction mixture as the hydrate. The hydrate is then mixed with concentrated sulfuric acid, the heavier acid layer is drawn off, and chloral is distilled through a fractionating column of moderate height.

Chlorination of a mole of ethanol requires 4 mol of chlorine, with the first serving to oxidize the ethanol to acetaldehyde.

$$CH_3CH_2OH + Cl_2 \rightarrow CH_3CHO + 2HCl$$

To withstand hot hydrochloric acid, the reaction vessels and piping for these processes are lined with a ceramic or other acid-resistant material, and valves of nickel–molybdenum alloys such as Hastelloy B are used.

4.4. Analysis

Technical-grade chloral ranges in purity from 94 to 99 wt %, with water being the main impurity. Other impurities sometimes present are chloroform, hydrogen chloride, dichloroacetaldehyde, and phosgene.

A common analytical method is to treat the chloral for 2 min with 1*N* sodium hydroxide, which cleaves chloral to chloroform and sodium formate; the excess alkali is then titrated with acid [59]. Alternatively, chloral is treated with quinaldine ethyl iodide [*606-55-3*] to form a blue cyanine dye whose quantity is measured spectrophotometrically [60].

Gas chromatography can be used for quantitative analysis of chloral and its hydrate, which breaks down to chloral on vaporization.

4.5. Legal Aspects

Chloral hydrate and other forms of chloral are classified by the U.S. Bureau of Narcotics and Dangerous Drugs (BNDD) as Schedule IV drugs, i.e., drugs of relatively low potential for abuse that lead only to limited physical or psychological dependence. The substance is approved by FDA as a habit-forming CNS depressant for use in adult and pediatric medicine [61].

To possess chloral, one must have a license from the BNDD, keep stored chloral locked up, and maintain records of where it goes and for what purposes. Licensees are periodically audited by the BNDD. Similar regulations are found in other countries [62]. The WHO has established a provisional guideline of 10 μg/L for chloral and chloral hydrate in drinking water. The drinking water guideline for Australia and New Zealand is 20 μg/L. The minimization of the concentration of all chlorination byproducts is encouraged in different countries and in the EU [63].

4.6. Uses and Occurrence

The principal use of chloral is in the production of the insecticide DDT. Much smaller amounts are used to make other insecticides (methoxychlor, naled, trichlorfon, dichlorvos), a herbicide (trichloroacetic acid), and hypnotic drugs (chloral hydrate, chloral betaine, α-chloralose, and triclofos sodium). Chloral is not known to occur as natural product. For the general public, the major route of exposure to this substance is from drinking water. Chloral hydrate and its metabolites are formed as byproducts when water is disinfected with chlorine [61, 63].

4.7. Economic Aspects

Chloral (as the hydrate) has been produced for use as a hypnotic drug in relatively low and gradually declining volume for many years. As an indication of the scale, U.S. production for this purpose was about 135 t in 1978. A far greater demand for chloral arose during World War II to produce DDT, which was proving highly successful in controlling the transmission of typhus and malaria. Demand for chloral for insecticide production rose rapidly after the war and reached a peak around 1963 when 40 000 t was produced in the United States. It then declined as insects developed resistance to chlorinated insecticides, some animals at the top of food chains showed adverse effects from concentrating DDT in their bodies, and public concern arose about the possibility of harmful effects in humans. The use of DDT was banned in the United States in 1972 and subsequently in many other countries, but it is still produced for use in the tropics. Consumption of chloral in the United States for other pesticides was 1400 t in 1972. Montrose Chemical Corporation was the only United States producer of chloral in 1978 [64].

5. Toxicology

5.1. Chloroacetaldehyde

Chloroacetaldehyde is toxic if swallowed and in contact with the skin and it is highly toxic by inhalation, causing instant to delayed death in experimental animals. The acute toxicities in laboratory animals are: rat, oral: LD_{50} = 89 mg/kg; rabbit, dermal: LD_{50} = 267 mg/kg [65]; and rat, inhalation: LC_{50} (1-h) = 650 mg/m^3 [66]. For mice exposed to flowing air containing chloroacetaldehyde vapor, the LT_{50} (exposure time lethal to 50 % of the test animals) was 2.57 min. A skin sensitization test with guinea pigs (maximization test) was negative. Due to the corrosive nature of the compound it had to be diluted to 0.002 % [67]. Even ca. 0.03 % aqueous solutions cause definite eye irritation, and a 0.5 % solution causes skin irritation.

No signs of toxicity were observed in rats, mice, rabbits, and guinea pigs after inhalative exposure to a chloracetaldehyde vapor concentration of 5.2 mg/m^3 (7 h/d, 5 d/week) over six months [68].

Chloroacetaldehyde is mutagenic in a variety of test systems, such as bacteria, molds, fish and mammalian cells, and in human lymphocytes. The compound exhibits alkylating properties and reacts with single-strand DNA [69]. In two initiation/promotion experiments in which chloroacetaldehyde was subcutaneously and dermally administered to mice, no increase in tumor incidence was observed [70, 71]. No carcinogenic effects have been observed after oral application (one application per week) of 12.5 mg/kg b.w. to females and males over 630 (female) and 636 d (male). In a carcinogenicity study with male mice, drinking water with 0.1 g/L chloroacetaldehyde was administered over two years. In this test an increased incidence of liver tumors could be observed [68].

Human experience has shown that chloroacetaldehyde vapor is extremely irritating to the skin, mucous membranes, and respiratory tract

[67]. A 40 % aqueous solution is corrosive to skin and it represents a serious hazard of eye injury. Upon skin contact it causes skin effects resembling burn blisters and tissue damage after a latency period of 1–2 h [72]. Human exposure to 32.6 mg/m^3 of chloroacetaldehyde in air leads within some minutes to lacrimation and nasal irritation [68].

The recommended TLV-STEL value in the USA is 1 ppm [5], this also being the maximum airborne concentration to which workers should be exposed. In Germany the former MAK value of 3 mg/m^3 (1 ppm) was annulled due to the carcinogenic potential of the substance. Adequate personal protection (goggles, gloves, protection mask) must be applied to prevent contact with this highly dangerous compound.

The substance is officially classified in the EU (Annex 1, published list of substances with a harmonised classification and labelling) in accordance with Council Directive 67/548/EEC as "Very Toxic" (T+) and "Dangerous to the Environment" (N) with R-phrases 24/25-26-34-40-50 (Toxic in contact with skin and if swallowed—Very toxic by inhalation—Causes burns—Limited evidence of a carcinogenic effect—Very toxic to aquatic organisms).

5.2. Dichloroacetaldehyde

Dichloroacetaldehyde is known to be irritating to breathe, but no formal testing has been reported. It should be handled carefully, as with the other two chloroacetaldehydes [65, 66].

5.3. Trichloroacetaldehyde (Chloral)

Chloral and chloral hydrate have the same physiological properties and can be discussed together. Chloral hydrate was extensively used for many years to induce sleep and to calm or sedate, but in recent decades it has been relegated to a minor role by the barbiturates, benzodiazepines, etc. (→ Hypnotics and → Sedatives).

Because of chloral hydrate's long use as a drug, much is known about the effects of chloral on humans [62]. It is a central nervous system depressant. In therapeutic doses of 0.5–1.0 g, it has little effect on respiration and blood pressure, but in toxic doses it depresses both. Ethanol enhances chloral's effects. Chloral is quite irritating to skin and mucous membranes. In the body it is readily reduced to trichloroethanol, which is responsible for most of chloral's physiological action. The trichloroethanol is excreted in the urine, mainly as the glucuronide. Oral doses of 4–30 g have been lethal to adults [62].

Rat studies indicate that chloral is highly toxic by inhalation [64]. The LC_{50} for 4-h exposure is 440 mg/m^3. On exposure to 78 mg/m^3 of chloral 4 h/d for 10 d, rats had severe lung injury and 6 of 10 died; similar results were obtained with 75 mg/m^3 for 2 h/d for 13 d. It is mutagenic in the Ames test. TLV and MAK values have not been assigned for chloral. However, the inhalation studies in rats indicate that chloral should be handled at least as carefully as chloroacetaldehyde [66].

The carcinogenic potential of chloral and chloral hydrate has been evaluated by the IARC with the conclusion that there is inadequate evidence in humans for carcinogenicity of chloral and chloral hydrate and limited evidence for carcinogenicity of chloral hydrate in experimental animals. Therefore chloral hydrate is not classifiable as to its carcinogenicity to humans (Group 3) [63].

Chloral and Chloral hydrate are officially classified in the EU (Annex 1, published list of substances with a harmonised classification and labelling) in accordance with Council Directive 67/548/EEC as "Toxic" (T) with R-phrases 25-36/38 (Toxic if swallowed—Irritating to eyes and skin).

1. Introduction

Chloroacetic acid and its sodium salt are the most industrially and economically important of the three chlorination products of acetic acid discussed in this review. The sections on physical and chemical properties, production, quality specifications, uses, and derivatives are reported separately for each of these three acids, whereas those on environmental protection, chemical analysis, containment materials, storage, transportation, and economic aspects are considered together.

2. Chloroacetic Acid

Chlorinated acetic acids have become important intermediates in organic synthesis because of the ease of substitution of the Cl atoms. Chloroacetic acid [*79-11-8*], $ClCH_2COOH$, M_r 94.50, monochloroacetic acid, chloroethanoic acid, is the most industrially significant [1]. It does not occur in nature and was first discovered as a chlorination product of acetic acid by N. LEBLANC in 1841. It was synthesized in 1857 by R. HOFFMANN, who chlorinated acetic acid by using sunlight to initiate the reaction. Discovery of other reaction accelerators, such as phosphorus, iodine, sulfur, or acetic anhydride, followed rapidly. Development of commercial processes, based mainly on acetic acid chlorination and later on acid hydrolysis of trichloroethylene, followed.

2.1. Physical Properties

Pure chloroacetic acid is a colorless, hygroscopic, crystalline solid, which occurs in monoclinically prismatic structures existing in the α-, β-, γ-, and also possibly the δ-form. Of these the

α-form is the most stable and the most important industrially.

Published physical data vary widely [1]. Some of the most common values are as follows:

Modification:	α	β	γ	δ
fp, °C:	62 – 63	55 – 56	50 – 51	43.8
Latent heat of fusion ΔH_f, kJ/mol:	19.38	18.63	15.87	–

Density:	d_4^{65} 1.3703 (liquid) d_4^{20} 1.58 (solid)
Refractive index:	n_D^{65} 1.4297
Surface tension:	σ 35.17 mN/m (100 °C)
Viscosity:	η 2.16 mPa · s (70 °C) 1.32 mPa · s (100 °C) 1.30 mPa · s (130 °C)
Degree of dissociation in water (potentiometric):	1.52×10^{-3} (25 °C)
Dielectric constant:	16.8 (100 °C)
Electrical conductivity, lowest value measured (70 °C):	3.1 µS/cm, (rises steeply if traces of water present)
Specific heat capacity:	c_p 144.02 J mol^{-1} K^{-1} (solid, 45 – 15 °C) 180.45 J mol^{-1} K^{-1} (liquid, 70 °C) 187.11 J mol^{-1} K^{-1} (liquid, 130 °C)
Heat of combustion:	ΔH_c 715.9 kJ/mol
Heat of evaporation:	ΔH_v 50.09 kJ/mol
Heat of formation (100 °C):	ΔH_f − 490.1 kJ/mol
Heat of sublimation (25 °C):	ΔH_{subl} 88.1 kJ/mol
Heat of solution in H_2O (16 °C):	
solid	$\Delta H_{solv,}$ − 14.0 kJ/mol
liquid	$\Delta H_{solv.}$ 1.12 kJ/mol
Flash point (DIN 51 758):	126 °C
Ignition temperature (DIN 51 794):	470 °C
Lower explosion limit in air (101.3 kPa):	8 vol%

Vapor pressure

t, °C	189	160	150	140	130	100	90	80
p, kPa	101.3	40.0	28.0	19.0	13.0	4.3	2.6	1.1

Solubility in water, α-form

t, °C	0	10	20	30	40	50	60
g/100 g soln.	71.0	76.0	80.8	85.8	90.8	95.0	99
g/100 g H_2O	245	317	421	604	987	1900	–

Chloroacetic acid has excellent solubility in water and good solubility in methanol, acetone, diethyl ether, and ethanol, but is only sparingly soluble in hydrocarbons and chlorinated hydrocarbons. Chloroacetic acid forms azeotropes with a number of organic compounds [2]. The freezing points of various binary mixtures of chloroacetic acids are shown in Figure 1.

Figure 1. Freezing points of binary mixtures
[a] Acetic acid (AA), chloroacetic acid (CAA), dichloroacetic acid (DCA), trichloroacetic acid (TCA). [b] Crystalline phase CAA. [c] Crystalline phase AA.

2.2. Chemical Properties

The high reactivity of the carboxylic acid group and the ease of substitution of the α-Cl atom are directly related. As a result, chloroacetic acid is a common synthetic organic intermediate, either as the acid itself or as an acid derivative (e.g., salt, ester, amide, hydrazide, etc.). Some important reactions that are used for industrial applications are as follows.

Reaction with inorganic bases, oxides, and carbonates or with organic bases gives salts; some salts form adducts with chloroacetic acid. Sodium chloroacetate [*3926-62-3*] is an important commercial product.

Chloroacetic acid esters are obtained by reaction with alcohols or olefins; methyl chloroacetate [*96-34-4*] and ethyl chloroacetate [*105-39-5*] are also important industrially. Chloroacetyl chloride [*79-04-9*] is produced from the acid by reaction with $POCl_3$, PCl_3, PCl_5, thionyl chloride ($SOCl_2$), phosgene ($COCl_2$), etc. (see Section 2.6.2.).

Chloroacetic acid reacts with chloroacetyl chloride to form bis(chloroacetic)anhydride [*541-88-8*], which can also be obtained by dehydration of chloroacetic acid with P_2O_5 or by reaction of chloroacetic acid with acetic anhydride. Chloroacetyl chloride forms mixed anhydrides with other carboxylic acids, e.g., acetic chloroacetic anhydride [*4015-58-1*].

Nucleophilic substitution of the chlorine atom is an important reaction when the product is used as an intermediate in organic syntheses. For example, heating neutral or basic aqueous solutions hydrolyzes the chlorine atom. This is an industrial method of producing glycolic acid [*79-14-1*] (hydroxyacetic acid) and diglycolic acid [*110-99-6*] (2,2′-oxydiacetic acid).

Heating the salts gives glycolide, 1,4-dioxine-2,5-dione [*502-97-6*]. Reaction with sodium or potassium hydrogen sulfide forms thioglycolic acid [*68-11-1*] and thiodiglycolic acid [*123-93-3*].

Reaction with ammonia gives either aminoacetic acid [*56-40-6*] (glycine) as the main product or, depending on reaction conditions, nitrilotriacetic acid [*139-13-9*]. If methyl chloroacetate reacts with ammonia at low temperature, chloroacetamide [*79-07-2*] is obtained.

Aromatic compounds, such as naphthalene, undergo electrophilic substitution with chloroacetic acid over suitable catalysts to form arylacetic acids.

Reaction with potassium cyanide in a neutral solution gives the commercially important cyanoacetic acid [*372-09-8*]. Reaction with potassium iodide forms iodoacetic acid [*64-69-7*].

The corresponding phenoxyacetic acids, some of which are of industrial importance, are made by phenol etherification in the presence of sodium hydroxide. Another industrially significant ether formation process gives carboxymethyl derivatives with a relatively high degree of etherification by reacting polysaccharides, such as cellulose, starch, guar, etc., in a strongly alkaline sodium hydroxide medium.

2.3. Production

A multitude of methods have been proposed and patented for production of chloroacetic acid [1], [3–15]. However, of all the methods described, only two are used on an industrial scale: the hydrolysis of 1,1,2-trichloroethylene [*79-01-6*] catalyzed with sulfuric acid (Eq. 1), and the catalyzed chlorination of acetic acid with chlorine (Eq. 2).

$$ClCH{=}CCl_2 + 2\,H_2O \xrightarrow[\text{Heat}]{H_2SO_4} ClCH_2COOH + 2\,HCl \qquad (1)$$

$$CH_3COOH + Cl_2 \xrightarrow[\text{Heat}]{\text{Cat.}} ClCH_2COOH + HCl \qquad (2)$$

The first method (Eq. 1) has become of technological significance; the second (Eq. 2) is older, historically and commercially, and currently is the more important process.

2.3.1. Hydrolysis of Trichloroethylene [13–15]

Equal amounts of trichloroethylene and 75 % sulfuric acid are reacted at 130 – 140 °C in a continuous process so that with complete trichloroethylene conversion, the resultant reaction mixture contains about 50 % chloroacetic acid and 1 – 2 % water. This blend is vacuum distilled to give pure chloroacetic acid. During this process the vapors are washed with water, which is returned to the sulfuric acid as a diluent. The resultant hydrogen chloride gas is washed with the fresh trichloroethylene and then purified by freezing and absorbing in water. Trichloroethylene (1500 – 1850 kg) and H_2SO_4 (600 kg, 95 %) gives 1000 kg of finished product and 700 – 750 kg of HCl gas as byproduct.

The trichloroethylene method produces highly pure chloroacetic acid free of di- or trichloroacetic acid. The purification procedure consists of separation from trichloroethylene, sulfuric acid, and water. Despite the purity of the chloroacetic acid formed, this method has fallen into disuse because of the high cost of trichloroethylene and the large amount of HCl produced. It is, however, still used on an industrial scale in several countries (Spain, former States of USSR, Romania, Yugoslavia, Japan, German Democratic Republic, etc.).

2.3.2. Chlorination of Acetic Acid

Synthesis. In this method the object is to convert acetic acid to chloroacetic acid with high

selectivity [1]. This is achieved by using suitable catalysts [13], [16–33]. When acetic anhydride is the catalyst, the reaction mechanism is as follows [22]:

$$(CH_3CO)_2O + Cl_2 \longrightarrow ClCH_2\overset{O}{\overset{\|}{C}}-O-\overset{O}{\overset{\|}{C}}CH_3 + HCl$$

$$ClCH_2\overset{O}{\overset{\|}{C}}-O-\overset{O}{\overset{\|}{C}}CH_3 + CH_3COOH \longrightarrow ClCH_2COOH + (CH_3CO)_2O$$

$$(CH_3CO)_2O + HCl \longrightarrow CH_3COCl + CH_3COOH$$

$$CH_3COCl + Cl_2 \longrightarrow ClCH_2COCl + HCl$$

$$ClCH_2COCl + CH_3COOH \longrightarrow ClCH_2COOH + CH_3COCl$$

Various inhibitors have also been proposed to suppress formation of dichloroacetic acid, which results from chlorination of chloroacetic acid in the crude mixture. This eliminates or reduces the purification process for technical grades [34–38].

Purification. The high degree of purity required for many products can only be obtained by separating the di- and trichloroacetic acids. Fractional distillation is unsuitable because the boiling points of the three chlorinated acetic acids are so close. Azeotropic distillation [39] and extractive distillation [40], [41] have been suggested for separating dichloroacetic acid; it is doubtful, however, that these methods are used.

One of the most widely practiced purification processes is *crystallization* without use of a solvent. It is based on the higher melting point of the α-modification of chloroacetic acid. The di- and trichloroacetic acids are removed in the mother-liquor.

Crystallization is carried out either in stationary finger crystallizers [42] or in agitated stirrer crystallizers. With the latter, the mother-liquor is separated from the crystal slurry after crystallization by using a centrifuge [43], [44]. The product is washed with water or acetic acid and discharged. The chloroacetic acid is usually melted and converted to flakes. In stationary machines, crystallization is carried out by using cold fingers. When all the chloroacetic acid has crystallized, the mother-liquor is drained; the pure crystalline product is then melted and flaked.

Another purification method that has been described is a thin-layer crystallization process with the raw material [45]. Use of a water content of 5 – 25 % without organic solvent is also possible [46].

Solvents have also been used for crystallization. Solvents, such as carbon tetrachloride [44], [47], dichloromethane [48], or hydrocarbons with three chlorine atoms (e.g., trichloroethylene), give crystals that are easy to filter [49].

Common to all of these crystallization methods is obtaining a mother-liquor consisting of acetic acid, chloroacetic acid, and di- and trichloroacetic acids. In the most favorable cases, this mixture is further chlorinated to form the industrially useful trichloroacetic acid (see Section 4.3).

In many instances, di- and trichloroacetic acids in either the mother-liquors, resulting from crystallization, or in the total chlorinated crude acid can be dechlorinated by catalytic hydrogenation at elevated temperature to form chloroacetic acid or acetic acid. Palladium on a carrier, such as carbon or silica gel, is normally employed.

When the reaction is carried out in the vapor phase, dichloroacetic acid is dechlorinated primarily to acetic acid [50]. However, when Pd is used on a finely dispersed, inert carrier in the liquid phase at 130 – 150 °C, dichloroacetic acid is dechlorinated selectively to form chloroacetic acid [51]. Modifications of this procedure, such as spraying the crude acid with the hydrogen gas under vacuum [52] or trickling the acid over the catalyst in the fixed bed [53], [54] have also been described.

Selectivity is increased if HCl is mixed with the crude acid before it and the circulating hydrogen contact the catalyst in the fixed bed [55]. Acid chlorides and anhydrides are saponified before dechlorination [56]. A particularly active and selective catalyst is Pd on silica gel (particle size 40 – 200 μm) [57]. Especially good results are obtained by employing a cocatalytically effective additive, such as sodium acetate [58]. The catalyst can be made more effective by enrichment of the nobel metal on its surface [59], [60]. Spent catalyst can be reactivated by treatment with chlorine [61], [62].

An industrial-scale chlorination process is shown in Figure 2. The mixture of acetic acid, acetic anhydride, and recycled acetyl chloride is chlorinated at 90 – 140 °C in reactor (a) or in several cascade reactors. Only traces of chlorine are still present in the HCl gas formed. Chloroacetic

Figure 2. Chloroacetic acid obtained by the chlorination – hydrogenation process
a) Chlorinating reactor; b) Condenser for acetic acid, acetic anhydride, chloroacetic acid; c) Condenser for acetyl chloride; d) Evaporator; e) Condenser for chloroacetic acid; f) Hydrogenation reactor; g) Hydrogen compressor; h) Condenser; i) Distillation column; j) Condenser for acetic acid

acid, acetic acid, and acetic anhydride are condensed by using water-cooled condensers (b) and then returned to the reactor. Acetyl chloride entrained in the HCl gas is condensed (c) in a subsequent low-temperature process and recycled. The HCl gas is further purified and usually converted to concentrated aqueous hydrochloric acid.

The crude acetic acids are vacuum distilled (d). Di- and trichloroacetic acids in the crude distilled material are dechlorinated (f) to chloroacetic acid at 120 – 150 °C, using a palladium catalyst and a large excess of hydrogen. Acetic acid is taken overhead from the vacuum fractionation column (i); the bottom product is pure chloroacetic acid.

A total of 660 – 780 kg of acetic acid and 780 – 1020 kg of chlorine are required per 1000 kg of pure acid, depending on the method used (in crystallization processes, the mother-liquors are regarded as lost). The process also gives 400 – 420 kg of HCl.

2.4. Quality Specifications

Chloroacetic acid is usually marketed to the following specifications:

Chloroacetic acid	min. 99.0 wt %
Dichloroacetic acid	max. 0.5 wt %
Acetic acid	max. 0.2 wt %
Sulfate	max. 0.5 wt %
Water	max. 0.2 wt %
Iron	max. 5 mg/kg
Lead	max. 1 mg/kg

Acid manufactured by the trichloroethylene method is virtually free of dichloroacetic acid; specially purified acid from the chlorination of acetic acid is marketed with an acetic acid content of max. 0.1 % and max. 0.3 % dichloroacetic acid. Technical grades contain up to 5 % dichloroacetic acid.

2.5. Uses

Most of the chloroacetic acid produced is used to manufacture several hundred thousand tons annually of *carboxymethyl cellulose* [*9004-32-4*], CMC (→ Cellulose Ethers, Chap. 6.2.). Starch can be reacted with chloroacetic acid to give carboxymethyl starch, which is as widely used as CMC (→ Starch). Other polysaccharides modified with chloroacetic acid are less important.

Another major application is the production of *herbicides* based on arylhydroxyacetic acids (→ Weed Control, → Chlorophenoxyalkanoic

Acids). These herbicides are some of the most widely used. Chloroacetic acid and methyl chloroacetate are also employed for making the insecticide dimethoate and the herbicides benazoline and methyl β-naphthyloxyacetate.

A third important outlet for chloroacetic acid is the manufacture of *thioglycolic acid* (mercaptoacetic acid [*68-11-1*]), obtained fro sodium or potassium hydrogen sulfide or other sulfur compounds (→ Thiols and Organic Sulfides). It is used as its salt, ester, or another derivative. The largest amount is employed to produce stabilizers for poly(vinyl chloride). Moreover, thioglycolic acid and its esters are used in hair cosmetics (→ Hair Preparations).

A minor use of chloroacetic acid is in the production of glycolic acid by saponification with an alkali hydroxide. Glycolic acid is used as an auxiliary in textile printing, leather treating, furs finishing, and as a component for cleaners; the butyl ester is employed as a paint additive, and glycolic acid esters acylated with *o*-phthalic acid half-esters are used as plasticizers (→ Plasticizers).

Apart from the major fields of application mentioned above, chloroacetic acid and its derivatives are used in a multitude of other organic synthetic reactions. For example, caffeine and barbiturates, which are important as sleeping tablets, can be made from cyanoacetic acid or its esters. Chloroacetic acid condenses with aromatic hydrocarbons to form arylacetic acids. Reaction with naphthalene gives 1-naphthylacetic acid as the main product and 2-naphthylacetic acid as the byproduct. Both substances promote plant growth. Chloroacetic acid also is important in the syntheses of coumarin and vitamin B_6 (→ Vitamins).

2.6. Derivatives

2.6.1. Sodium Chloroacetate

Physical, Chemical Properties. The sodium salt $ClCH_2COONa$ [*3926-62-3*], M_r 116.5, is of particular importance. It is colorless and slightly hygroscopic, and has good storage stability. It dissolves readily in water (44 wt % at 20 °C), giving a neutral solution. It has limited solubility in other polar solvents and is insoluble in nonpolar solvents. It hydrolyzes in water, depending on temperature and time, forming glycolic acid and sodium chloride.

Production. This salt is manufactured by reacting sodium carbonate with chloroacetic acid in batches or in a continuous process [63], [64].

In exceptional cases, localized superheating (about 150 °C) may occur during the reaction. If it does, slow thermal decomposition can take place, producing sodium chloride and polyglycolide as the main products with pronounced evolution of gas.

Another method of manufacturing sodium chloroacetate is spraying molten chloroacetic acid together with 50 % caustic soda solution into a spray drier [65].

The production of salts of chloroacetic acids in fluidized beds has been described [66].

Uses. The uses for sodium chloroacetate are virtually the same as those for its free acid. The amount of salt required is less and depends on whether the free chloroacetic acid is used as an 80 % aqueous solution or as a melt.

2.6.2. Chloroacetyl Chloride

Physical Properties. Chloroacetyl chloride [*79-04-9*], $ClCH_2COCl$, M_r 112.95, is a colorless, highly corrosive liquid that has a pungent odor and fumes when exposed to moist air; *bp* 105 °C (101.3 kPa), d_4^{20} 1.42, n_D^{20} 1.454.

Production. Chloroacetyl chloride is usually manufactured from chloroacetic acid by reaction with phosphorus trichloride, thionyl chloride, sulfuryl chloride, or phosgene. It is also obtained by chlorination of acetyl chloride in the presence of stronger aliphatic acids, preferably chloroacetic acids, or from sodium chloroacetate and the usual chlorinating agents.

One patent describes the manufacture of chloroacetyl chloride by chlorination of a mixture of 5 – 50 wt % acetyl chloride in acetic anhydride at 70 – 100 °C [67]. Another claims reaction of chloroacetic acid and trichloroethylene in the presence of iron(III) chloride and hydrochloric acid at 150 °C and 2 MPa [68]. Chloroacetyl chloride also has been obtained in 97.1 % yield and with a purity of 99.8 % by reacting chloroacetic acid with phosgene in the

presence of palladium chloride at 110 °C [69]. Chlorination of ketene, which must be present in an excess of at least 50 %, at 100 – 200 °C gives chloroacetyl chloride with less than 7 % dichloroacetyl chloride [70]. Chloroacetyl chloride can also be made from 1,2-dichloroethylene and oxygen by using catalysts, such as bromine.

Uses. Chloroacetyl chloride is used for many syntheses, e.g., to make adrenaline, chloroacetic acid esters, and the anhydride.

2.6.3. Chloroacetic Acid Esters

Physical Properties. The *methyl ester* [*96-34-4*], $ClCH_2COOCH_3$, M_r 108.53, is of particular importance. It is a colorless liquid with a pungent odor, *bp* 130 – 131 °C (101.3 kPa), *fp* – 32.7 °C, d^{20} 1.236, soluble in alcohol and ether, and only sparingly soluble in water.

Also important is the *ethyl ester* [*105-39-5*], $ClCH_2COOCH_2CH_3$, M_r 122.55, *bp* 144.2 °C (101.3 kPa), *fp* – 26.0 °C, d^{20} 1.159, insoluble in water, and readily soluble in alcohol and ether.

Production. These esters can be manufactured from chloroacetic acid and either methyl or ethyl alcohol. In another method, trichloroethylene is converted to ethyl 1,2-dichlorovinyl ether, which can be readily hydrolyzed to form chloroacetic acid ethyl ester.

Uses. The reactivity of the ester, which is greater than that of the free acid, makes it suitable for many syntheses, e.g., sarcosine, chloroacetamide, thioglycolic acid ester [71] for pharmaceuticals (vitamin A), and crop protection agents (dimethoate). Condensation with aldehydes and ketones gives glycide esters [72]. Other uses are the synthesis of heterocyclic compounds, e.g., 2-phenylimino-4-oxooxazolidine from the ester and phenyl urea [73], and the well-known condensation of chloroacetic acid and its esters with thioureas to form pseudothiohydantoins.

2.6.4. Chloroacetamide

Physical Properties. Chloroacetamide [*79-07-2*], $ClCH_2CONH_2$, M_r 93.52, colorless crystalline needles, *bp* 224 °C (101.3 kPa), *fp* 121 °C, is soluble in water and alcohol, and sparingly soluble in all nonpolar solvents.

Production. Chloroacetamide is obtained on an industrial scale by reaction of methylchloroacetate with ammonia at low temperature [74]. Manufacture from chloroacetic acid and cyanamide at 150 – 200 °C also has been described [75].

Uses. Chloroacetamide is a versatile intermediate. In addition, it has biocidal properties and, therefore, is used as an industrial preservative. Because of its good solubility in water, chloroacetamide is a particularly suitable biocide for protection of the aqueous phase, e.g., in drilling fluids [76], in water-containing paints [77], and as a wood preservative [78]. Its insecticidal action on aphids [79] and its use as a hardener for urea and melamine resins [80] have also been described.

Various derivatives have the same biocidal effect as chloroacetamide. For instance, *N*-octadecylchloroacetamide is used as an antimicrobial plasticizer [81].

3. Dichloroacetic Acid

3.1. Physical Properties

Dichloroacetic acid [*79-43-6*], 2,2-dichloroethanoic acid, $Cl_2CHCOOH$, M_r 128.95, *bp* 192 °C (101.3 kPa), 102 °C (2.7 kPa), *fp* 13.5 °C, d_4^{20} 1.564, n_D^{20} 1.466, vapor pressure 0.19 kPa (at 20 °C), dissociation constant 5×10^{-2} mol/L (at 18 °C), is a colorless, highly corrosive liquid that gives off acidic vapors, which irritate the mucous membranes. It is miscible with water in any proportion. Dichloroacetic acid is readily soluble in the usual organic solvents, such as alcohols, ketones, hydrocarbons, and chlorinated hydrocarbons.

3.2. Chemical Properties

The two chlorine atoms of dichloroacetic acid are susceptible to displacement. For instance,

with aromatic compounds, diaryl acetic acids are formed, and with phenol, diphenoxy acetic acids are the products. However, dichloroacetic acid is less prone to hydrolysis than chloroacetic acid. In the manufacture of carboxymethyl celluloses and starches, the dichloroacetic acid impurity in the chloroacetic acid gives rise to cross-linking, which is either desirable or undesirable, depending on the use of the end product.

3.3. Production

The most cost-effective production method is the hydrolysis of dichloroacetyl chloride (see Section 3.6.1). Moreover, 98 % dichloroacetic acid can be obtained in 90 % yield by hydrolysis of pentachloroethane with 88 – 99 % sulfuric acid [82] or by oxidation of 1,1-dichloroacetone with nitric acid and air [83]. Extremely pure dichloroacetic acid can be produced by hydrolysis of the methyl ester [84], which is readily available by esterification of crude dichloroacetic acid. Furthermore, dichloroacetic acid and ethyl dichloroacetate can be obtained by catalytic dechlorination of trichloroacetic acid or ethyl trichloroacetate with hydrogen over a palladium catalyst [85].

Separation of pure dichloroacetic acid from the other chloroacetic acids cannot be carried out by physical methods, especially fractional distillation, because the differences in boiling points, particularly between di- and trichloroacetic acid, are too small. The ester mixtures, on the other hand, can be satisfactorily fractionated in efficient distillation columns. In addition, mixtures of the salts of the three chloroacetic acids can be washed with water, alcohol, or water – alcohol solutions. The dichloroacetate can be dissolved preferentially and acidified to give pure dichloroacetic acid.

Dichloroacetic acid can be produced in the laboratory by reacting chloral hydrate and potassium or sodium cyanide:

$$Cl_3CCHO + H_2O + KCN \longrightarrow HCN + KCl + Cl_2CHCOOH$$

3.4. Quality Specifications

Dichloroacetic acid is a colorless liquid that is marketed, for instance, by Hoechst, with the following technical data:

Content	ca. 99 %
bp at 101.3 kPa	192 °C
Water, max.	0.3 %
fp	> 12 °C

3.5. Uses

Dichloroacetic acid is used as a test reagent for analytical measurements during fiber manufacture [poly(ethylene terephthalate)] and as a medicinal disinfectant (substitute for formalin).

Dichloroacetic acid, particularly in the form of its esters, is an important intermediate in organic synthesis. It is a reactive starting material for the production of glyoxylic acid, dialkoxy and diaroxy acids, and sulfonamides.

3.6. Derivatives

3.6.1. Dichloroacetyl Chloride

Physical Properties. Dichloroacetyl chloride [*79-36-7*], $Cl_2CHCOCl$, M_r 147.40, is a colorless liquid, which has an unpleasant odor and fumes when exposed to moist air; *bp* 107 °C (101.3 kPa), d_4^{16} 1.5315, n_D^{16} 1.4638, vapor pressure 3.06 kPa (at 20 °C).

Chemical Properties. Dichloroacetyl chloride undergoes not only reactions typical of acid chlorides, but also displacement reactions of the chlorine atoms in the 2-position. The chemistry of dichloroacetyl chloride and its derivatives is analogous in certain respects to that of glyoxylic acid. Thus, dichloroacetyl chloride reacts with ammonia and amines to form amino acids, with alcohols to form ester acetals and acetals, with benzene to form diarylacetic acids, and with phenols to form diphenoxyacetic acids.

Production. Dichloroacetyl chloride is produced by *oxidation of trichloroethylene.* Oxidation with oxygen to form a mixture of dichloroacetyl chloride and chloral has been known since the early 1900s [86]. More recent patents describe methods to manufacture dichloroacetyl chloride of > 98 % purity, e.g., at 65 – 200 °C and 0.2 – 2 MPa in the presence of free-radical

initiators [87], using catalytic quantities of azo compounds and amines [88], and initiating oxidation with UV light and only adding organic nitrogen bases in quantities of 0.005 – 0.05 % once oxidation has begun [89]. Correspondingly, chloroacetyl chloride and trichloroacetyl chloride can be produced from 1,2-di- and tetrachloroethylene, but these methods are of little industrial significance because the products can be obtained more easily by other processes.

Furthermore, dichloroacetyl chloride is manufactured from pentachloroethane and fuming sulfuric acid or from chloroform and carbon dioxide in the presence of aluminum chloride at high pressure [90]. It has also been produced from ketene and chlorine in the presence of sulfur dioxide [91].

Uses. Dichloroacetyl chloride is used to manufacture dichloroacetic acid (see Section 3.3). In addition, it can be employed for the production of esters and anhydrides. It is used as the starting material to manufacture pharmaceuticals, such as sulfonamides and antibiotics (chloramphenicol), and to produce crop protection agents.

3.6.2. Dichloroacetic Acid Esters

Physical Properties. *Methyl dichloroacetate* [*116-54-1*], $Cl_2CHCOOCH_3$, M_r 142.98, *bp* 143.3 °C (101.3 kPa), d_4^{20} 1.3808, n_D^{20} 1.4428. *Ethyl dichloroacetate* [*535-15-9*], $Cl_2CHCOOCH_2CH_3$, M_r 157.00, *bp* 158.5 °C (101.3 kPa), d_4^{20} 1.2821, n_D^{20} 1.4386.

Chemical Properties. These esters are highly reactive and, for example, condense with aldehydes and ketones in the presence of dilute metal amalgams to form α-chloro-β-oxyacid esters, which can be converted to the corresponding aldehydes via glycide esters [92]. Dichloroacetic acid esters are readily saponified by boiling water.

Production. These esters are obtained by the usual esterification methods. The methyl and ethyl esters are best produced by alcoholysis of dichloroacetyl chloride.

Uses. These esters are employed as intermediates in the manufacture of chloramphenicol (→ Antibiotics), dichloroacetamide, and crop protection agents, and are employed as paint resin solvents. The glyceryl and ethylene glycol esters also serve as plasticizers for cellulose derivatives.

The vapors of dichloroacetic acid esters are heavier than air and can form explosive mixtures with air.

4. Trichloroacetic Acid

4.1. Physical Properties

Pure trichloroacetic acid [*76-03-9*] forms hygroscopic, rhombohedral crystals that are extremely soluble in water and soluble in many organic solvents; Cl_3CCOOH, M_r 163.40, *bp* 197.6 °C (101.3 kPa), *bp* ca. 107 °C (2.8 kPa), *fp* 59.2 °C, d_4^{60} 1.630, n_D^{65} 1.459.

4.2. Chemical Properties

The complete substitution of the hydrogen atoms on the methyl radical by chlorine makes trichloroacetic acid a strong acid ($K = 2\times10^{-1}$ mol/L); it also makes the chlorine atoms less easily substituted than those of chloroacetic acid and dichloroacetic acid. Trichloroacetic acid decomposes to chloroform and carbon dioxide when its aqueous solution is exposed to heat. The decomposition is particularly fast in the presence of organic or inorganic bases. When water is absent, aniline, resorcinol, and activated carbon can catalyze the decomposition. Purely thermal decomposition takes place only when the boiling point has been exceeded, resulting in the formation of chlorinated hydrocarbons, carbon monoxide and dioxide, and phosgene. Trichloroacetic acid salts with inorganic and many organic bases are known. They decompose when heated in the presence of water to form chloroform.

4.3. Production

Trichloroacetic acid is produced on an industrial scale by chlorination of acetic acid or

chloroacetic acid mother-liquors at 140 – 160 °C [93]. If necessary, calcium hypochlorite is added as a chlorination accelerator [94]. There are conflicting views concerning adding heavy metal salts as chlorination catalysts. Examples of catalysts that have been used are iron and copper compounds, which are precipitated with sulfuric acid or phosphoric acid if decomposition of the reaction mixture occurs [95]; 2 % phosphoric acid [96]; and catalysts and UV light [97]. Trichloroacetic acid has also been produced without catalysts [98], [99].

The crude product, containing about 95 % trichloroacetic acid, is best isolated by crystallizing the melt, removing the mother-liquor with most of its impurities, and increasing the purity by centrifugation or recrystallization.

4.4. Quality Specifications

Trichloroacetic acid is marketed in various degrees of purity. The specifications in Table 1 are typical (see below).

4.5. Uses

The main application for trichloroacetic acid is production of its sodium salt, which is used as a selective herbicide and in formulations with 2,4-D and 2,4,5-T preparations as a total herbicide.

Trichloroacetic acid also is employed as an etching or pickling agent in the surface treatment of metals, as a swelling agent and solvent in the plastics industry, as an albumin precipitating agent in medicine, as an auxiliary in textile finishing, and as an additive to improve high-pressure properties in mineral lubricating oils. Because it is strongly corrosive, trichloroacetic acid is used to remove warts and hard skin and to treat various skin afflictions [101]. Trichloroacetic acid, particularly its esters, are important starting materials in organic syntheses. The acid undergoes numerous color reactions that can serve to identify a wide range of organic compounds [102].

4.6. Derivatives

4.6.1. Trichloroacetyl Chloride

Physical Properties. Trichloroacetyl chloride [*76-02-8*], Cl_3CCOCl, M_r 197.9, *bp* 118 °C (101.3 kPa), d_4^{20} 1.620, n_D^{20} 1.4695, is similar to dichloroacetyl chloride.

Chemical Properties. The acid chloride can be hydrolyzed at 75 – 85 °C with water to form the free acid and hydrolyzed with ammonium hydroxide or concentrated sodium carbonate solution to form the salts.

Production. The acetyl chloride is prepared from trichloroacetic acid and various inorganic acid chlorides (e.g., $SOCl_2$, PCl_3) or with P_2O_5

Table 1. Typical quality specifications

and HCl. More useful methods are the oxidation of tetrachloroethylene with fuming sulfuric acid, oxygen, or fuming nitric acid and sulfuric acid at 18 – 20 °C [103], or from the reaction of pentachloroethane and dry oxygen under UV light [104]. It has been obtained in 37 % yield from carbon tetrachloride and carbon monoxide in the presence of aluminum chloride at 200 °C and high pressure [105].

The most common production method is the gas-phase, photochemical oxidation of tetrachloroethylene with oxygen. The reaction is initiated with UV light, with radioactive irradiation, or it is sensitized with chlorine or iodine [106].

Uses. Trichloroacetyl chloride can be used for the manufacture of the esters and the anhydrides of trichloroacetic acid.

4.6.2. Trichloroacetic Acid Esters

Only the methyl and ethyl esters are of industrial interest. They can be used as solvents, if necessary, and for the production of the amide and polyalcohol esters, which have been suggested for use as plasticizers. *Methyl trichloroacetate* [*598-99-2*], $Cl_3CCOOCH_3$, M_r 177.43, *bp* 153 °C (101.3 kPa), d_4^{20} 1.4864, n_D^{20} 1.4572. *Ethyl trichloroacetate* [*515-84-4*], $Cl_3CCOOCH_2CH_3$, M_r 191.45, *bp* 167.5 °C (101.3 kPa), d_4^{20} 1.3823, n_D^{20} 1.4505.

4.6.3. Trichloroacetic Acid Salts

The sodium salt is the only one of industrial importance.

Physical Properties. Sodium trichloroacetate [*650-51-1*], TCA, sodium TCA, STCA, NaTA, $Cl_3CCOONa$, M_r 185.40, is a colorless salt that decomposes at temperatures below the melting point. The salt is very soluble in water and methanol and soluble in polar solvents. The solubility in water at − 5 °C is 50 wt %, at 20 °C 60 wt %, and at 40 °C 70 wt %.

Chemical Properties. The salt is stable in the dry state and at normal storage temperature. Hydrolytic cleavage takes place in aqueous solution:

$$Cl_3CCOONa + H_2O \longrightarrow Cl_3CH + NaHCO_3$$

At the boiling point, this reaction takes place quantitatively within an hour and is used for quantitative analysis of sodium trichloroacetate [107]. At 20 – 25 °C the aqueous solution is relatively stable; with a 50 % solution only ca. 1 % is hydrolyzed in 4 – 6 weeks.

In aprotic solvents, such as 1,2-dimethoxyethane, the reactive intermediate dichlorocarbene is formed as the primary product at elevated temperature (ca. 80 °C) [108]:

$$Cl_3CCOONa \longrightarrow NaCl + CO_2 + :CCl_2 \quad (3)$$

When phase-transfer catalysis is used, the dichlorocarbene can add, for example, across olefinic double bonds to give dichlorocyclopropane derivatives [108]. If dichlorocarbene is formed in the absence of other acceptors, it reacts with additional sodium trichloroacetate:

$$Cl_3CCOONa + :CCl_2 \longrightarrow Cl_3CCOCl + CO + NaCl \quad (4)$$

Consequently, the main products formed during the thermal decomposition of sodium trichloroacetate (combination of Eqs. 3 and 4) were sodium chloride, trichloroacetyl chloride, carbon monoxide, and carbon dioxide; also observed were chloroform, carbon tetrachloride, and traces of phosgene [109].

Thermal decomposition is exothermic (42 kJ/mol) and starts between 125 and 170 °C. This decomposition reaction is quenched by adding water; hydrolysis then takes place.

Production. Sodium trichloroacetate is produced industrially by neutralizing trichloroacetic acid with sodium hydroxide solution or sodium carbonate [110], [111].

Uses. Sodium trichloroacetate, together with reducing agents and traces of heavy-metal salts, is recommended as a polymerization catalyst for vinyl compounds [112]. It is useful as a dyeing auxiliary because of the formation of $NaHCO_3$ during hydrolysis [113]. It also improves absorption of disperse dye systems on polyester and cellulosic fibers [114]. Moreover, in diazo papers developed by heat, sodium trichloroacetate is used to liberate base at 100 – 200 °C [115].

Most important, however, is its application as a selective herbicide to control monocotyledonous annual or perennial weeds [116–118]. As a soil-applied herbicide its half-life is 1 – 2 months [119]. For use as a crop protection agent, a minimum content of 95 % sodium trichloroacetate is required. Because the salt in powder form causes severe irritation, the product is usually marketed as granules [120].

5. Environmental Protection

The waste gases formed during chlorination of acetic acid depend on the degree of chlorination. When purification is done by fractional crystallization, less than 1 % of unreacted acetic acid is necessary in the crude acid. In this case chlorine occurs in these waste gases; recovery of the chlorine has been described [121].

Formation of chlorinated hydrocarbon impurities also depends on the production method used. They form as a result of decarboxylation and occur particularly in the manufacture of trichloroacetic acid.

In the trichloroethylene method and in the manufacture of dichloroacetic acid by catalytic oxidation of trichloroethylene, residues of the starting materials are always present in the waste gases. Such waste gases are purified by adsorption on activated charcoal or are incinerated.

Moreover, the high sulfate salt load can be a wastewater problem in the trichloroethylene method. Chlorinated acetic acids are biodegradable by activated sludge floc, but they can cause serious interference particularly in community wastewater treatment plants that have not been bioprepared. Preventing effluent contaminated with products of acetic acid chlorination from draining into public sewer systems is essential.

Spills of chlorinated acetic acids and their derivatives, resulting, for instance, from transport accidents, should be contained with inert materials (sand or earth) and collected for safe disposal, or neutralized with agents, such as Na_2CO_3 or $NaHCO_3$. Any contaminated soil must be removed (the chlorinated acetic acids are strong pollutants to groundwater). Waste material should be taken to an approved disposal facility (special landfill disposal, incinerator, or wastewater treatment plant).

Chloroacetic acid is flammable at higher temperature and forms explosive mixtures with air (lower explosion limit 8 vol%). The two other acids are nonflammable. If the acids are involved in a fire, the decomposition gases of trichloroacetic acid and dichloroacetic acid may contain phosgene, whereas chloroacetic acid gases are free of phosgene.

6. Chemical Analysis

Rapid analysis of the purity of mono-, di-, and trichloroacetic acid is adequately provided by determining the melting and freezing points, particularly when the melting depression is caused by known contamination.

Quantitative analysis of chloroacetic acid should include total acidity and a separate determination of dichloroacetic acid, sulfuric acid, hydrochloric acid, water, and heavy metals, as well as total chlorine content by approved methods. From these determinations acetic acid and chloroacetic acid content can be calculated.

Dichloroacetic acid can be determined with a high degree of accuracy by saponification with strong base and subsequent manganometric titration. Dichloroacetic acid values are exaggerated in the presence of trichloroacetic acid. If trichloroacetic acid is present, preliminary saponification with dilute base is advisable.

Acetic acid and dichloroacetic acid can be directly separated and quantitatively determined by gas chromatography. In addition to these two acids, trichloroacetic acid can also be detected in the form of its methyl ester by gas chromatography. Dichloroacetic acid and acetic acid in the presence of chloroacetic acid can also be determined accurately by HPLC [122]. This method is not recommended for chloroacetic acid itself because titration to determine total chlorine content is more accurate.

Trichloroacetic acid is determined by hydrolysis in acid solution to chloroform and quantitative determination of the hydrogen ions needed for saponification. Formation of a deep-red complex from pyridine and chloroform can be used for a colorimetric method [123]. Nitron [1,4-diphenyl-3-(phenylamino)-1*H*-1,2,4-triazolium hydroxide] produces a salt with trichloroacetic acid, which is suitable for detecting the acid [124].

Dichloroacetic acid can be determined by polarography in mixtures with trichloroacetic acid [125]. Large amounts of chloroacetic acid interfere with the determination.

Determination of heavy metals in all chlorinated acetic acids and derivatives is carried out by familiar methods, such as atomic absorption or colorimetry. For lead, inverse voltametry is also used.

7. Containment Materials, Storage, and Transportation

Because of the corrosiveness of these chemicals, most metals are unsuitable for use as *container materials.* Thus, chlorination is carried out in ceramic-lined, lead-coated steel containers or in glass-lined vessels. Pipelines are made of glass-lined steel or steel lined with polytetrafluoroethylene (PTFE) or perfluoroalkoxy (PFA) polymers (e.g., tetrafluoroethylene). Silver that has been rendered inert by a silver chloride layer can be used for parts of the equipment (e.g., valves, heat exchangers, distillation column linings, stirrers). Tantalum and titanium (with certain temperature limits) are other suitable metallic materials. Carbon (Diabon) and glass are effective materials for heat exchangers. In addition to PTFE and PFA/TFA, fluorinated ethylene – propylene copolymers (FEP), poly(vinyl chloride), polyethylene, and polypropylene can be used at relatively low temperature and for aqueous solutions.

The aqueous solution can be handled in special stainless steel or rubber-lined steel containers at temperatures below 40 °C. Iron with a baked phenolic resin coating can be used below 100 °C. In the trichloroethylene method, steel (cast iron) is an adequate material in many parts of the process.

During *storage and transportation,* high corrosivity and, with chloroacetic acid, toxicity must also be considered. Chlorinated acetic acids and their derivatives are classified as dangerous substances. They are subject to nearly all national and international handling regulations. Containers must be labeled in the stipulated manner. In the case of chloroacetic acid, the most important forms that are shipped are the melt (in glass-lined railroad cars or titanium-lined tank trucks) and the 80 % aqueous solution (in stainless steel or rubber-lined tank trucks and containers).

Crystallized, flaked chloroacetic acid and trichloroacetic acid are obtained by utilizing chilled rolling flakers and, more recently, with chilled conveyor-type flakers; the coarser flakes manufactured in this manner tend to agglomerate less and, therefore, are preferred. Flakes are packed in multilayer paper sacks or in polyethylene bags contained in fiberboard or iron drums. Small quantities are supplied in polyethylene containers or in glass bottles. Dichloroacetic acid and most of its liquid derivatives usually are shipped in iron drums with polyethylene inner containers.

If stored in a cool, dry place, the chlorinated acetic acids and their derivatives are stable almost indefinitely, although the crystallized products have a marked tendency to agglomerate.

8. Economic Aspects

The worldwide manufacturing capacity for chloroacetic acid is estimated at 420 000 t/a, divided as follows:

Western Europe Federal Republic of Germany (ca. 23 %), Finland, France, United Kingdom, Netherlands, Sweden, Spain	ca. 50 %
Eastern bloc	ca. 22 %
Asia	ca. 12 %
United States	ca. 11 %
South America, South Africa	ca. 5 %

Because French manufacturers have switched to the acetic acid method, 80 – 85 % of worldwide production is now manufactured by the chlorination method. One manufacturer uses 1,1-dichloroethene/chloroacetyl chloride as the starting material, whereas the remainder are probably still using the older trichloroethylene process.

Recognized manufacturers are AKZO, Atochem, Billerud/Uddeholm, Courtaulds Acetate/UK, Cros, Dow, Hercules, Hoechst, and Mätselliito.

Worldwide production cannot be determined precisely because no statistics have been published. Worldwide consumption was estimated

to be 290 000 t in 1983. The main consuming region is Western Europe (ca. 125 000 t in 1983), followed by the Eastern bloc, the United States, and Japan. An increase is expected in some areas in the next few years.

Accurate figures are not available on the amounts of chloroacetic acid and its derivatives used for different applications. However, by far the largest amount goes into the production of carboxymethyl cellulose, starch, and polysaccharides. This is followed by herbicides based on phenoxyacetic acids (2,4-D, MCPA, 2,4,5-T) and thioglycolic acid (ca. 70 % of which is used as esters in industry and about 30 % as salts in cosmetics). All the other applications (glycolic acid, glycine, vitamins, and derivatives of chloroacetic acid for organic syntheses) account for probably not more than 10 % of annual production.

Dichloroacetic acid is of little economic importance. More significant are its acid chloride and methyl ester, which are used as intermediates in the manufacture of agrochemicals and chloramphenicol.

In the case of trichloroacetic acid, only the sodium salt is important. About 21 000–23 000 t/a are used worldwide as a selective herbicide.

9. Toxicology and Occupational Health

Chloroacetic Acid and Chloroacetate. Chloroacetic acid is a corrosive solid material. The lowest published LD_{50} is 76 mg/kg for oral administration to rats [126]. Single oral administration of lethal doses resulted in apathy and loss of body mass. Death occurred several days after administration [127].

Acute inhalational exposure of rats led to eye and pulmonary irritation. The irritation threshold is 23.7 mg/m^3. The LC_{50} is 180 mg/m^3 [128].

Prolonged inhalation of chloroacetic acid resulted in reduced body mass, reduced oxygen consumption, hemoglobinemia, and inflammation of the respiratory tract. A threshold limit value for chloroacetic acid of 1 mg/m^3 is recommended if these experimental animal findings are taken as a basis [128]. However, the ACGIH has not established a TLV; neither has an MAK been set.

Repeated intake of 0.1 % chloroacetate in the diet led to depressed growth curves and an increased level of liver glycogen [129]. A major metabolic pathway for chloroacetic acid is reaction with glutathion, finally yielding thiodiacetic acid [130]. One report has shown that chloroacetic acid elevates mutant rates in the mouse lymphoma forward mutation assay [131].

Dichloroacetic Acid and Dichloroacetate. Dichloroacetic acid, a clear colorless liquid, is corrosive to the skin and mucous membranes. Its oral LD_{50} is 2820 mg/kg for rats, which is of the same order of magnitude as that for trichloroacetic acid. Dichloroacetic acid is able to penetrate rabbit skin with a dermal LD_{50} of 797 mg/kg [126]. The lowest oral LD_{50} reported for dichloroacetate is 4480 mg/kg for fasted rats [127]. Sodium dichloroacetate was examined in a 3-month oral toxicity study in rat and dogs. Both species manifested toxic effects, such as depressed appetites and increased body mass, degenerative changes of testicular germinal epithelium, hind limb muscular weakness or paralysis, and brain lesions. Cessation of administration brought about an amelioration or recovery from all effects except brain lesions. Dogs proved to be more sensitive than rats, showing toxic effects at 50 mg kg^{-1} d^{-1}. The CNS observations are extremely relevant in light of a report that described polyneuropathy of a 21-year-old man whose severe hypercholesterolemia had been treated orally with dichloroacetate (50 mg/kg) for 16 consecutive weeks. The polyneuropathy was characterized by weakness of facial, finger, and lower extremity muscles, by diminished deep tendon reflexes, and by slowing of nerve conduction velocity. The neuropathy improved when the therapy was stopped [132].

Dichloroacetate demonstrated low-grade mutagenicity in the Ames Salmonella/mammalian microsome mutagenicity test [133].

Trichloroacetic Acid and Trichloroacetate. Trichloroacetic acid is a strong protein precipitant and is corrosive to the skin and eye. The solid material is not readily absorbed through the skin [133]. The lowest reported oral LD_{50} in rats for trichloroacetic acid was 3320 mg/kg

and 5060 mg/kg for trichloroacetate. The lowest lethal dose of trichloroacetate for female dogs was 1590 mg/kg with toxic effects, such as salivation, emesis, sedation, ataxia, and coma [134], [135]. A 4-h exposure to 4800 mg/kg trichloroacetate in ambient air did not result in any clinical symptoms or macroscopically detectable pathologic lesions in rats, guinea pigs, rabbits, and cats [135].

Medical reports of acute exposure effects of trichloroacetic acid showed mild to moderate skin and eye burns [136]. In humans, trichloroacetate was an irritant to skin and mucous membranes. Opaqueness of the cornea may occur. Oral ingestion led to intestinal colics, salivation, emesis, diarrhea, muscular weakness, anorexia, and apathy [135].

Little relevant chronic toxicity data exists for trichloroacetic acid. The toxicological profile of airborne trichloroacetic acid is assumed to be dominated by lesions of mucous membranes of the upper respiratory tract. A TLV-TWA of 1 ppm, 7 mg/m^3 is suggested, based largely on analogy to 2,2-dichloropropionic acid (TLV-TWA 1 ppm, 6 mg/m^3) [136].

Trichloroacetic acid strongly binds to plasma proteins. High concentration in blood is capable of displacing drugs from protein-binding sites. Because of this systemic effect of potential drug displacement from plasma proteins, a TLV of 1 – 2 ppm may be accepted for trichloroacetic acid [134].

For trichloroacetate, a provisionally tolerated daily intake of 0.075 mg/kg body mass has been established. This limit value takes into account the results of a subchronic dog feeding study with concentrations in food of $\geq$ 2000 mg/kg, resulting in loss of body mass, malaise, necrosis of gingival and buccal mucosae, changes in white blood count, pathologic urine findings, lesions of the liver and myocardium, atrophy of skeletal muscle, and impairment of spermiogenesis. The nontoxic effect level was 500 mg/kg in the diet [135].

On the basis of available in vitro data, trichloroacetate does not exert mutagenic effects [135].

1. Introduction

Chloroamines are inorganic or organic nitrogen compounds that contain one or more chlorine atoms attached to a nitrogen atom. A familiar example is monochloroamine (NH_2Cl), which has been known since the beginning of the 19th century.

Chloroamines are used in synthetic reactions and as bleaching agents, disinfectants, and bactericides because they function as chlorinating agents and oxidants. Since chloroamines are safer and easier to handle than chlorine gas or metal hypochlorites, they are widely used in the purification of drinking water and as sanitizing agents in swimming pools. *N*-Chloroisocyanuric acids and 1-bromo-3-chloro-5,5-dimethylhydantoin have become important in the sanitizing and disinfectant markets, replacing calcium hypochlorite, 1,3-dichloro-5,5-dimethylhydantoin, and chloramine-T.

2. Chemical Properties

N-Chloroamines can act as oxidizing agents by absorbing two electrons:

$$Cl^+ + 2e^- \longrightarrow Cl^-$$

Thus, an *N*-chloroamine oxidizes hydriodic acid to liberate iodine, and this reaction is used for the quantitative analysis of *N*-chloroamines:

$$RR'NCl + 2HI \longrightarrow HCl + RR'NH + I_2$$

The theoretical *available chlorine content* of an *N*-chloroamine is expressed as twice the mass fraction of chlorine in the molecule. However, for practical purposes, the value is expressed as the equivalent of elemental chlorine as determined by the oxidizing ability of the N-chloroamine.

The quantitative hydrolysis constant (*K* value) of an *N*-chloroamine is expressed by the equation below, and is generally in the range $10^{-4} - 10^{-10}$ (Table 1).

$$RR'NCl + H_2O \rightleftarrows RR'NH + HOCl$$

$$K = \frac{c_{RR'NH} \cdot c_{HOCl}}{c_{RR'NCl}}$$

Table 1. *K* values of important *N*-chloroamines

N-Chloroamine	CAS registry no.	*K* value
Trichloroisocyanuric acid	[*87-90-1*]	6.7×10^{-4}
1,3-Dichloro-5,5-dimethylhydantoin	[*118-52-5*]	2.5×10^{-4}
N-Chlorosuccinimide	[*128-09-6*]	6.6×10^{-5}
Dichloramine-T	[*473-34-7*]	8.0×10^{-7}
Chloramine-T	[*127-65-1*]	4.9×10^{-8}
Monochloroamine	[*10599-90-3*]	2.8×10^{-10}

The *K* value is used to express the bactericidal power of *N*-chloroamines, which depends on their generating hypochlorous acid in water.

The N – Cl bonds of *N*-chloroamines are covalent and are readily hydrolyzed by water with release of hypochlorous acid. They are thermally unstable; many do not melt congruently and can explode at elevated temperature. Trichloroamine (nitrogen trichloride, NCl_3) is particularly unstable and can cause explosions when present as an impurity in other *N*-chloroamines. *N*-Chloroamines should be stored cold and pro-

10.1002/14356007.a06_553

tected from light, water, amines and ammonium compounds, strong acids and bases, and easily oxidized organic materials.

3. Reactions

Many *N*-chloroamines are useful as reagents or intermediates in organic synthesis. For example, *N*-chloroamides of organic carboxylic acids can be reduced by alkali to the corresponding amines in good yield. This reaction, called the Hofmann degradation, is widely used for the synthesis of aromatic, heterocyclic, and alicyclic amines [1–5]:

$$RCONH_2 \xrightarrow{Cl_2} RCONHCl \xrightarrow{OH^-} RNH_2$$

N-Chloroureas can be converted into hydrazines by treatment with base in an alcohol or water solution [6], [7]:

$$RNHCONHCl \xrightarrow[OH^-]{R'OH} RNHNHCO_2R' \text{ or } RNHNH_2$$

N,N-Dichlorocarbamates, Cl_2NCOOR, are useful chlorinating agents and can also be added to dienes [8], [9]:

$$RO_2CNCl_2 + CH_2{=}CH{-}CH{=}CH_2 \longrightarrow RO_2CNClCH_2CH{=}CHCH_2Cl$$

They are also the starting materials for the synthesis of *N*-halo-*N*-metallocarbamidates, which are intermediates in the synthesis of carbamate derivatives of physiologically active substances [10–14]:

$$C_2H_5O_2CNCl_2 \xrightarrow{C_2H_5O_2CNH_2} C_2H_5O_2CNHCl \xrightarrow[\text{metal}]{\text{Alkali}} C_2H_5O_2CNNaCl$$

8-Azaisatoic anhydride (**3**), an intermediate to several agrichemicals, is synthesized in high yield by chlorinating 2,3-pyridinedicarboximide (**1**) to *N*-chloro-2,3-pyridinedicarboximide (**2**), followed by treatment with alkali [15], [16]:

N-Chloroamidines and *N*-chloroguanidines, which have excellent bactericidal and fungicidal activity, are widely used as intermediates in the syntheses of heterocyclic ring systems such as imidazoles, thiazoles, and oxadiazoles [17–21].

where R″ = alkyl

4. Inorganic *N*-Chloroamines

Monochloroamine [*10599-90-3*], NH_2Cl, M_r 51.47, *mp* −66 °C, is a colorless liquid with a strong pungent odor. It is more stable in aqueous solution than dichloroamine [*3400-09-7*], $NHCl_2$, M_r 85.91, or trichloroamine [*10025-85-1*], NCl_3, M_r 120.36, *mp* −92 °C, *bp* 70 °C, and is mainly used for primary purification of drinking water. It is also used in organic synthesis as an oxidizing agent for trisubstituted phosphines [22]. All of these *N*-chloroamines are prepared in pH-controlled reactions by the action of hypochlorous acid or chlorine on ammonium salts [23], [24].

$$NH_3 + x\,HOCl \longrightarrow NH_{3-x}Cl_x + x\,H_2O \qquad x = 1, 2, 3$$
$$NH_3 + 3\,Cl_2 \longrightarrow NCl_3 + 3\,HCl$$

Extreme care should be taken when any of these *N*-chloroamines in pure form are isolated, because they are unstable and explosive in the pure state, even at room temperature.

N-Chlorosulfamic acid (**4**) [*17172-27-9*], M_r 131.55, *N,N*-dichlorosulfamic acid (**5**) [*17085-87-9*], M_r 166.00, and sodium *N*-chloroimidodisulfonate (**6**) [*67700-32-7*], M_r 255.56, are prepared from sulfamic acid and hypochlorous acid. They are widely used as disinfectants and bleaching agents for paper [25].

$ClNHSO_3H$	Cl_2NSO_3H	$ClN(SO_3Na)_2$
4	**5**	**6**

The activities of fabric-bleaching compositions based on **6** are described in detail in [26], [27].

5. *N*-Chloroisocyanuric Acids

N-Chloroisocyanuric acids (chloroisocyanurates), such as 1,3,5-trichloro-1,3,5-triazine-2,4,6(1*H*,3*H*,5*H*)trione [*87-90-1*], trichloroisocyanuric acid, Symclosene, TCC (**7**), and 1,3-dichloro-1,3,5-triazine-2,4,6(1*H*,3*H*,5*H*)trione sodium salt [*2893-78-9*], sodium dichloroisocyanurate, DCC-Na (**8**), have become increasingly important as disinfectants because they are more stable and easier to handle than metal hypochlorites. Table 2 gives physical properties of TCC and DCC-Na.

TCC

7

DCC–Na

(DCC–Na · 2 H_2O[*51580–86–0*])

8

Table 2. Physical constants of TCC and DCC-Na [28]

Property	TCC [*87-90-1*]	DCC-Na [*2893-78-9*]
Physical form	White powder	White powder
Formula	$(ClNCO)_3$	$Cl_2Na(NCO)_3$
M_r	232.44	219.98
mp	234 °C (decomp.)	225 °C (decomp.)
Available chlorine		
Theoretical (%)	91.5	64.5
Typical value	90.0	62.0
pH (1 % aqueous solution)	2.7 – 3.3	6.2 – 6.8
Solubility (g/100 g)		
Water (25 °C)	1.0	30.0
Acetone (30 °C)	35.0	0.5

In particular, TCC and DCC-Na have acquired a substantial share of the market traditionally served by calcium hypochlorite, pine oils, quaternary ammonium salts, and phenols.

5.1. Production and Chemical Properties

N-Chloroisocyanuric acids are prepared by continuous reaction of chlorine with isocyanuric acid in aqueous sodium hydroxide at 0 – 15 °C. Careful control of pH and reaction temperature are essential to prevent the formation of explosive NCl_3 [29], [30]. Trichloroisocyanuric acid (TCC) is gradually decomposed in an alkaline medium, yielding NCl_3, $NHCl_2$, and NH_2Cl. Both DCC-Na and its dihydrate have high water solubility compared with TCC; the dihydrate is thermally more stable than DCC-Na. The dihydrate of DCC-Na is obtained by cooling a saturated aqueous solution of DCC-Na (45 °C) to 10 °C.

5.2. Uses

The oxidizing and bioactive properties of the *N*-chloroisocyanuric acids derive from the hypochlorous acid that is slowly released from them in water. These compounds are used for many purposes such as nonshrinking treatment of wool, disinfectants for swimming pools, cleaning and sterilizing of bathrooms, and laundry bleach.

Cleaners and sanitizers based on *N*-chloroisocyanuric acids contain the following other components: phosphates, sodium metasilicates, surfactants, and such neutral salts as sodium sulfate and sodium carbonate. They are effective in removing oil and protein on stainless steel; they are also recommended for dishwashing in hotels, hospitals, restaurants, and food factories.

TCC and DCC-Na are sold in the form of granules or tablets. In general, TCC is used to achieve an active chlorine level of 1 – 2 mg/L in swimming pools, and DCC-Na a level of 100 – 300 mg/L in food processing.

Economic Aspects. In 1985, the estimated world production of *N*-chloroisocyanuric acids was 85 000 t. Suppliers include Olin, Monsanto, CDF Chimie, Chlorchem, Delsa, Nissan Chem. Ind., and Shikoku Chem. Ind. The demand for these compounds is increasing by 8 – 10 % per year for swimming pool use and 3 – 5 % per year for food processing.

6. Other Organic *N*-Chloroamines

1,3-Dichloro-5,5-dimethylhydantoin [*118-52-5*], Dactin, Halane (BASF Wyandotte), M_r 197.03, *mp* 132 °C, theoretical chlorine content 77.6 %, water solubility 2.1 g/L, is prepared by passing chlorine through an aqueous solution of 5,5-dimethylhydantoin [31], [32]. It has been used since the 1930s as a bactericide and disinfectant, but its use and market are decreased by the use of other dominant *N*-chloroamines, such as TCC and Di-Halo. 1-Bromo-3-chloro-5,5-dimethylhydantoin (**9**) [*16079-88-2*], M_r 241.48, *mp* 130 °C (decomp.), pH 2.88 (0.1 % solution), water solubility 2 g/L (20 °C), is prepared by successive bromination and chlorination of 5,5-dimethylhydantoin [33], [34]. The compound is a stable white powder, and the formation of chloroamines is not observed in weakly basic aqueous solution.

9

It has become widely used at an active halogen level of 0.5 – 3 mg/L for swimming pool disinfectants because of its stability in water and in storage, as well as its broad bactericidal spectrum [35], [36]. It is marketed under the name of Di-Halo (Aquabrom/TESCO; Division of Great Lakes Chemicals). Production in 1985 was estimated at ca. 2500 t, growing at a rate of 10 – 20 % per year. 1-Chloro-2,5-pyrrolidinedione (**10**) [*128-09-6*], *N*-chlorosuccinimide, M_r 133.54, *mp* 150 – 151 °C, is a white solid that is sparingly soluble in ether, chloroform, and carbon tetrachloride. It has 50 – 54 % available chlorine and is used principally as a chlorinating agent in organic synthesis [37].

10

N-Chloroglycolurils have been studied as protective agents against poison gas and are prepared by condensation of 1,2-diketones with urea followed by chlorination. An important example is 2,4,6,8-tetrachloro-2,4,6,8-tetrazabicyclo[3.3.0]octane-3,7-dione (**11**) [*776-19-2*], M_r 279.82.

11

1,3,4,6-Tetrachloro-3α,6α-diphenylglycoluril [*51592-06-4*], Iodogen (**12**), M_r 431.94, is used as a bactericide and as an oxidizing agent in syntheses of peptides [38–40].

12

3-Chloro-4,4-dimethyl-2-oxazolidinon (**13**) [*58629-01-9*], M_r 149.50, is an example of a new class of *N*-chloroamines that are being investigated as disinfectants [41], [42].

13

Sodium *N*-chloro-*p*-toluenesulfonamide (**14**) [*127-65-1*], chloramine-T, M_r 227.67 (hydrate: *mp* 175 °C; explosive), has an available chlorine content of 25 %. It is prepared in 75 – 95 % yield by passing chlorine into a sodium hydroxide solution of *p*-toluenesulfonamide [43], [44]. It is a strong electrolyte in acid solution and a good oxidizing agent in base. It is fairly soluble in water, and practically insoluble in benzene, chloroform, and ether. The compound reacts readily with mustard gas to yield a harmless crystalline sulfimide; chloramine-T derivatives are being studied as protective agents against poison gas [14].

14

Other examples of this group of compounds are *N*-chlorobenzenesulfonamide (**15**) [*127-52-6*], chloramine-B, M_r 213.64 (hydrate: *mp* 180 °C; explosive), and *N*-dichlorobenzenesulfonamide (**16**) [*473-29-0*], dichloramine-B, M_r 226.08, *mp* 76 °C (decomp.).

15

16

N,N′,N″-Trichloromelamine (**17**) [*12379-38-3*], M_r 229.46, *mp* 175 °C (decomp.), theoretical chlorine content 92.8 %, is used as a sterilizing agent to a smaller extent because of its low solubility in water.

17

N-Chlorinated derivatives of various amino acids are being studied as bleaching agents and bactericides [45–47].

7. Toxicology

The toxicity of *N*-chloroamines is very important because of their widespread use in drinking water, swimming pools, and food processing. When they are used in water that contains organic compounds, special care must be taken to prevent the formation of halomethanes, which are weak carcinogens. The formation of halomethanes in water is measured by the head space method, purge trap method, or solvent extraction, followed by analysis with GC (electron capture detector) or GC – MS [48], [49].

Most *N*-chloroamines irritate the eyes, moist skin, and the upper respiratory tract. Solutions of N-chloroisocyanuric acids containing up to 100 ppm of available chlorine are not toxic, irritating, or sensitizing. However, ingestion of the pure solid or a fresh strong suspension attacks the stomach lining. The isocyanuric acid formed after hydrolysis has low toxicity. Table 3 gives a few acute toxicity values.

Table 3. Acute toxicity of *N*-chloroamines

Compound	LD_{50}, mg/kg (rat, oral)	Reference
TCC	1300	[28]
DCC-Na	1420	[28]
1,3-Dichloro-5,5-dimethylhydantoin	542	[50]
N-Chlorosuccinimide	2700∗	[51]

∗ Minimum lethal dose.

Chloramine-T is a skin irritant; it is highly toxic when absorbed in the blood and should, therefore, be used only in diluted solution. Monochloroamine is widely used as a primary disinfectant for drinking water because of the low rate at which it forms halomethanes from organic compounds in the water. It has a long duration of action, although its specific bactericidal activity is rather low. However, it has been implicated as a mutagen and as a toxic agent for aquatic life, and the U.S. Environmental Protection Agency proposes to prohibit its use in drinking water [52]. 1-Bromo-3-chloro-5,5-dimethylhydantoin is less toxic to test fish species than 1,3-dichloro-5,5-dimethylhydantoin [53].

1. Introduction

Chloroformic esters are also known as chloroformates, chlorocarbonates, or chlorocarbonic esters (Chemical Abstracts Service calls them carbonochloridic acid esters). They are represented by the general formula ClCOOR, wherein R can be any alkyl or aryl group [1, 2]. They were first described by Dumas in 1833 [3]. They are highly reactive compounds and, since about 1950, have attained considerable importance as intermediates in organic syntheses [4].

2. Physical Properties

Commercially important chloroformic esters are predominantly colorless liquids having boiling points only slightly higher than the corresponding alcohols. The esters of low-boiling alcohols have pungent odors and are highly volatile.

In general, chloroformic esters have densities greater than 1.00 and are immiscible or only slightly miscible with water. They are, however, miscible with inert organic solvents. The order of thermal stability of the different types of esters is aryl > primary alkyl > secondary alkyl > tertiary alkyl. The phenyl ester decomposes only slightly at its boiling point of 189 °C, but the *tert*-butylester starts decomposing at 10 °C. Decomposition is catalyzed by metal salt impurities (iron, aluminum, copper, cobalt, magnesium, and nickel) and by tertiary amines. It can proceed in two ways and lead to two different sets of products both of which include gases, which cause increased pressure in closed containers.

$$ClCOOCH_2CH_2R \rightarrow CH_2 = CHR + HCl + CO_2$$
$$ClCOOCH_2CH_2R \rightarrow ClCH_2CH_2R + CO_2$$

where R may be any alkyl or aryl group

The physical properties of the commercially important chloroformic esters are given in Table 1.

3. Chemical Properties

Chloroformic esters exhibit the characteristic chemical properties of acid chlorides. They react with all nucleophiles including carbon acids. They react with water to produce hydrogen chloride and their corresponding alcohol. Moist chloroformic esters are, therefore, highly corrosive. They form carbonates (→ Carbonic Esters) and thiocarbonates in reactions with alcohols and mercaptans, respectively. Chloroformic esters react with carboxylic acids to form carboxylic acid anhydrides [6] and with primary and secondary amines to form carbamic acid esters [7].

Their reactions with alkali peroxides form dialkyl peroxydicarbonates [8]. Bis(chloroformic) esters obtained from glycols or dihydric phenols undergo reactions with dihydric alcohols to produce polycarbonates, with dicarboxylic acids to give polyesters, or with amino compounds to yield polyurethanes [1]. They react with nitriles to form amides [9].

* No physical data reported; identification by IR and NMR data [5].

4. Production

The most important method used to produce chloroformic esters is the reaction of phosgene with anhydrous alcohols.

$$ROH + COCl_2 \rightarrow ClCOOR + HCl$$

where R may be any alkyl or aryl group

The reaction with aliphatic alcohols proceeds with no need for hydrogen chloride acceptors or catalysts. The conversion of phenols with phosgene occurs less readily. The reaction depends on the presence of catalysts such as alkali salts [10], tertiary amines or quaternary ammonium salts [11], carboxylic acid amides (e.g., dimethylformamide or *N*-methylpyrrolidone) [12], or organic phosphorus compounds (e.g., triphenylphosphine, triphenylphosphine oxide) [13] and is carried out discontinuously at high temperature. The formation of carbonates by a competing reaction depends on the nature of the catalyst. Alkali salt catalysts lead to substantially more carbonate formation than phosphorus compounds. To suppress carbonate formation, the reaction heat is rapidly carried off and an excess of phosgene is maintained in the reaction zone.

Continuous and discontinuous processes are available for the preparation of chloroformic esters. In the laboratory the synthesis is carried out by passing alcohol into liquid phosgene at low temperature. The discontinuous method is generally not applicable to commercial syntheses for reasons of safety. In special cases where this method is employed, an inert diluent is required, e.g., the ester itself [14] or aliphatic, aromatic, or chlorinated hydrocarbons, and the alcohol and phosgene enter the reaction vessel simultaneously. The solvent, containing dissolved hydrogen chloride and excess phosgene, is removed by distillation [15]. The discontinuous method is used for the production of chloroformic esters from glycols and the conversion of sterically hindered or acid-sensitive alcohols. An auxiliary base, e.g., pyridine or dimethylaniline, increases the reaction rate.

The continuous procedure is the method of choice for the commercial production of aliphatic chloroformic esters. It can be carried

out in either cocurrent or countercurrent flow. The required amounts of alcohol and phosgene can be passed in cocurrent flow into a circulation reactor, cascade vessel [16], or nozzle atomizer [17], or the components can react in the gas phase [18, 19]. The countercurrent method is carried out in a packed column [20, 21] because hydrogen chloride and excess phosgene then escape from the top of the column and the liquid ester collects at the bottom. A product of 99 % purity can be obtained if the temperature in the reaction zone is maintained below 10 °C for the formation of the methyl ester or below 20 °C for the ethyl ester [21]. Esters of alcohols with an intermediate chain length ($C_3 - C_8$) are produced at 30 – 70 °C. Purity of 97 – 99 % and a yield greater than 90 % are achieved with esters of primary alcohols, whereas the more unstable esters of secondary and tertiary alcohols give 70 – 80 % yields.

Chloroformic esters can also be made by reacting alcohols with carbon monoxide and chlorine under pressure [22], by chlorinating formates or thioesters, by reacting phosgene with aldehydes, or by reacting phosphorus pentachloride with cyclic carbonates [2, 4]. Chloroformic esters with β-chlorine atoms are made by reacting phosgene with the corresponding epoxide [1], by reacting alcohols with trichloroacetyl chloride [1], and by cleaving α-keto sulfoxides with hydrogen chloride [2, 23]. The crude ester is purified by distillation unless, as is the case for the aliphatic esters, thermal instability precludes this method.

5. Safety

Safety precautions necessary for the handling of phosgene apply to the production of chloroformic esters. The exhaust gas is hydrolyzed and then burned. Undesirable substances, e.g., phenol, are extracted from wastewater.

Some chloroformic esters are classified as dangerous working substances [24] and may be handled only when protective clothing and equipment are used (gas masks with filter B, rubber gloves, etc.). They must not enter the atmosphere or the water supply. If spilled or leaked, they can be hydrolyzed by alkaline substances. Vapors must be destroyed in a scrubber with alkali or with water in the presence of activated carbon or by incineration. Clothing that comes into contact with chloroformic esters must be removed immediately. Any part of the body that is touched by a chloroformic ester must be washed well with water immediately. All important chloroformic esters are flammable; they form explosive mixtures with air. Electrostatic charges must, therefore, be avoided.

6. Quality Specifications and Analysis

Commercial products have concentrations of 97 – 99 wt %. Along with small amounts of carbon dioxide, hydrogen chloride, phosgene, and alkyl chlorides, the main impurities are the corresponding carbonates. The amounts of carbon dioxide, hydrogen chloride, and alkyl chlorides increase with the duration of storage, depending on the stability of the ester. A purity of 97 % is adequate for most applications. If especially pure product is required, 99 % pure, distilled methyl chloroformate is available. The methyl ester can be distilled under normal pressure, but the ethyl ester requires vacuum conditions and continuous distillation. Esters obtained from secondary or tertiary alcohols are not sufficiently stable to be purified by distillation. They must be washed with cold water and dried with calcium chloride.

The quantitative analysis of chloroformic esters can be carried out by titration, gas chromatography, or high-performance liquid chromatography (HPLC). High-boiling or thermally labile esters are determined by titration. They are treated with aniline in methanol, and the liberated hydrochloric acid is titrated with sodium hydroxide. They can also be treated with excess dibutylamine in chlorobenzene; the remaining amine is then back-titrated with hydrochloric acid.

Bivalent esters are assayed by reacting them with an aniline derivative, e.g., methylaniline, and using HPLC to measure the dicarbamate formed.

7. Storage and Transportation

The thermal stability of chloroformic esters is important for storage and transportation. Esters

of primary alcohols and phenols are stable if free of moisture and metal salts. Traces of moisture and heat can generate hydrogen chloride and increase the internal pressure. For this reason, containers should not be exposed to direct sunlight. The esters of secondary and tertiary alcohols (e.g., isopropyl ester or cyclohexyl ester) require rapid transportation and no more than brief storage because they are unstable.

The storage temperature should be maintained below 10 °C and the product used as soon as possible. Iron drums lined with polyethylene or lead-lined tank cars are used to transport chloroformic esters. The methyl and ethyl esters are mentioned in the regulations for the transportation of dangerous materials (GGVE), clause 6.1, class 4. The corrosiveness, toxicity, and flammability (primary label) of the esters must be declared on the container and EEC guidelines require that dangerous working substances be provided with an additional dangerous-materials label giving instructions for handling (R and S label).

8. Uses and Economic Aspects

Chloroformic esters are highly reactive and can be used as intermediates in the synthesis of numerous compounds. They are employed in the production of unsymmetrical carbonic acid esters (→ Carbonic Esters) such as diethylene glycol bis(allyl) carbonate [25], which is an intermediate in the synthesis of plastics of excellent optical quality. Other aliphatic or aromatic bis(chloroformic) esters are also used to make plastics such as polycarbonates (Makrolon) [26, 27] and polyurethanes having a high temperature resistance [1, 28]. Alkyl and aryl esters of chloroformic acid serve as catalysts in the presence of initiator radicals in the low-pressure polymerization of ethylene [29]. The methyl and ethyl esters are used as solvents in the photographic industry. They are also employed in the production of carbamates that are used to synthesize dyes (e.g., Resolin dyes), drugs, (e.g., the tranquilizer meprobamate [*57-53-4*]), veterinary medicines (e.g., furazolidone [*67-45-8*] or rintal [*58306-30-2*]), herbicides, (e.g., betanal [*13684-63-4*] and betanex [*13684-56-5*]), and insecticides, (e.g., Sevin [*63-25-2*]).

The herbicide IPC, isopropyl *N*-phenylcarbamate [*122-42-9*], is made from isopropyl chloroformate. Another important application is the preparation of the dialkyl peroxycarbonates used as catalysts in the sodium peroxide production of PVC, poly(vinyl chloride) [*78320-64-6*] [30]. Such commercially important peroxycarbonates as ethyl [*14666-78-5*], *n*-butyl [*16215-49-9*], isopropyl [*105-64-6*], cetyl [*26322-14-5*], cyclohexyl [*1561-49-5*], and 4-*tert*-butylcyclohexyl peroxycarbonate [*26523-73-9*] can be made from the corresponding chloroformates. Methyl chloroformate is the starting material for the synthesis of the preservative velcorin (dimethyl pyrocarbonic ester) [*4525-33-1*]. Phenyl chloroformate is used in the production of Sirius dyes [31]. Benzyl chloroformate is used to substitute the carbobenzyloxy protecting group on amino functions of amino acids in peptide synthesis [32], on hydroxyl groups [33], and on hydrazino groups [34]. The protecting group is easily removed by hydrogenolysis over a catalyst [35].

Ethyl chloroformate is the most important of these esters. It reacts with ethyl xanthate [*140-90-9*] to produce diethylxanthogen formate [*3278-35-1*] and diethylxanthic anhydride [*2905-52-4*], which are used in the flotation of ores [8]. Ethyl chloroformate is also used as a stabilizer for PVC and in the production of modified penicillins, e.g., binotal [*69-53-4*]. It is used to produce carboxylic acid anhydrides from carboxylic acids [6], secondary amines from tertiary amines [36], and nitriles from amides [9] and to make heterocyclic compounds [37].

The cyclohexyl, 4-*tert*-butylcyclohexyl, butyl, and cetyl esters of chloroformic acid are used almost exclusively to produce peroxydicarbonates. The majority of the isopropyl ester produced is also used for this purpose (total production is several thousand metric tons per year).

Chloroformic esters are not produced on a large scale. Their economic importance is due to their usefulness as intermediates in organic syntheses. The largest producers in Western Europe are BASF, Société Nationale des Poudres et Explosifs, Hoechst, and Bayer. In the United States, Chemetron Corp., Essex Chem. Corp., Minerec Corp., and PPG Industries are the major producers. Hodogaya Co. in Japan and Chemolimpex in Hungary are also major suppliers. The pro-

duction capacity in Western Europe is ca. 20 – 25 kt/a.

9. Toxicology

Chloroformic esters cause acute reactions of the respiratory tract and mucous membranes. Contact with the gastrointestinal tract or absorption by the skin leads to less toxic reactions (Table 2). Chloroformic esters burn the skin, leaving its surface hard and stained brown [38 – 42], and they are corrosive to the eyes [39 – 42]. Inhalation of vapors of short-chain chloroformic esters results in coughing, choking, and respiratory distress, and with some chloroformates, such as methyl chloroformate, inhalation can cause death as a result of the onset of pulmonary edema, which may appear only several hours after exposure, as seen in phosgene poisoning [39, 43, 44]. The inhalative toxicity of chloroformic esters decreases with increasing chain length [39 – 42]. Cetyl chloroformate is not toxic even when saturated air is inhaled [45, 46]. The introduction of a halogen in the α-position of aliphatic esters increases their inhalative toxicity [47]. Inhalation of methyl chloroformate (shortest chain length) in a 90-d study caused marked damage throughout the respiratory tract in rats. Exposure to 8 mL/m^3 (31 mg/m^3) caused some lethality. No treatment-related toxicological changes were observed in organs other than the respiratory tract. Irrespective of the number of exposures, the no observed adverse effect concentration (NOAEC) was 0.4 mL/m^3 (1.6 mg/m^3) for 3, 10, 20, and 65 exposures in this study. The same NOAEC was found in a 28-d study in rats [39]. In an exploratory subacute inhalation study with ethyl chloroformate, 20 exposures to 1 mL/m^3 (4.5 mg/m^3) were tolerated by rats without remarkable findings, whereas 10 exposures to 20 mL/m^3 (90 mg/m^3) resulted in signs of irritation of the respiratory tract and poor general condition [40, 48]. Butyl chloroformate had an NOAEC of 1.8 mL/m^3 (10 mg/m^3) in a 28-d inhalation study [42].

On the basis of these studies, the German MAK Commission established MAK values of 0.2 mL/m^3 (0.78 mg/m^3) for methyl chloroformate and 0.2 mL/m^3 (1.1 mg/m^3) for butyl chloroformate. Furthermore, both substances have been assigned to pregnancy risk group C, i.e., substances for which "there is no reason to fear a risk of damage to the embryo when MAK and BAT values are observed" [39, 42]. Further limit values exist in the Netherlands and Australia/UK: ethyl chloroformate 1 mL/m^3 (4.4 mg/m^3) [49, 50], isopropyl chloroformate 1 mL/m^3 (5.1 mg/m^3) [51], and 2-ethylhexyl

chloroformate 0.13 mL/m^3 (7.9 mg/m^3) [49, 52].

In Salmonella/microsome tests, with or without metabolic activation, neither methyl nor ethyl, nor propyl nor butyl chloroformate revealed a mutagenic potential. Only with methyl and butyl chloroformate was a chromosomal aberration test conducted in V79 cell lines of the Chinese hamster. Both substances showed no clastogenic effect in the absence of metabolic activation, whereas in the presence of metabolic activation the aberration rate was increased, a result that was not reproducible in an independent study with butyl chloroformate [39 – 42].

In an exploratory carcinogenicity study, male Sprague – Dawley rats underwent whole-body exposure to ethyl chloroformate at levels of 1.5, 3.0, or 6.0 mL/m^3 (ca. 6.75, 13.5, and 27 mg/m^3 air) 6 h/d, 5 d per week for 30 d and were subsequently held for life-span observation. One out of 50 animals exposed to 6 mL/m^3 and examined at the age of ca. 2 years (700 d) were found to have squamous cell carcinoma of the nasal mucosa. None of the 98 controls exposed to test-substance-free air under the same conditions exhibited tumors of that type. Among animals treated with 6 mL/m^3 ethyl chloroformate, 15 out of 50 (30 %) exhibited squamous metaplasia of the nasal mucosa, and 45 out of 50 (90 %) had rhinitis; in the control group, 9 out of 98 (9.1 %) displayed squamous metaplasia, and 80 out of 98 (ca. 82 %) had rhinitis. The investigators did not analyze their data for statistical significance. Further exploratory carcinogenicity studies in female ICR/Ha Swiss mice (30 – 50 mice per group) receiving lifetime (18 – 22 months) dermal or subcutaneous administrations of ethyl chloroformate showed no increase in tumor incidence compared with controls. Ethyl chloroformate was administered to the 30 – 50 animals per group dermally three times per week at doses of 3, 4.3 or 5.5 mg per administration or subcutaneously once weekly at doses of 0.3 or 1.1 mg per administration. According to the investigators, the highest doses corresponded to the maximum tolerated dose (MTD) in each case. In parallel, the same investigators carried out an initiation – promotion test with single dermal application of 5.5 mg ethyl chloroformate followed by a 14-d treatment-free period and lifetime dermal applications of phorbol myristate acetate (PMA) as promoter three times per week. According to the investigators, animals treated with ethyl chloroformate and PMA exhibited marginally increased tumor incidences (6 out of 50 animals developed tumors, 4 papillomas, and 2 squamous carcinomas). It is unclear precisely what amount of PMA was used to treat animals on initiation with ethyl chloroformate and, consequently, which PMA control group was used for comparison. Therefore, the evaluation lacks clear plausibility [40].

In Germany the MAK Commission has assigned ethyl chloroformate to Category 3B of carcinogenic substances (i.e., "Substances that cause concern that they could be carcinogenic for man but cannot be assessed conclusively because of lack of data. The classification in Category 3 is provisional.") [53].

1. Introduction

Chlorohydrins are compounds with one or more chlorine and hydroxyl groups in the nonaromatic portion of their structure. The compounds of greatest industrial importance are the propylene chlorohydrins and glyceryl chlorohydrins (see Table 1). Ethylene chlorohydrin is no longer an important intermediate for the production of ethylene oxide, one of the classic commodity chemicals.

Nomenclature. Many different names for the various chlorohydrins appear in the literature. Some of these *synonyms* for the major chlorohydrins are given in Table 1.

2. Physical Properties

Most dilute solutions of chlorohydrins in water have a somewhat sweet, pleasant odor, particularly 3-chloro-1,2-propanediol (**5**), 1,3-dichloro-2-propanol (**7**), and 3-chloro-1-propanol (**4**). The general physical properties of the more significant chlorohydrins are listed in Table 2.

3. Chemical Properties

Chlorohydrins undergo reactions which are characteristic of both alcohols and alkyl chlorides. This combination is responsible for the most common reaction of chlorohydrins, which is *dehydrochlorination to form epoxides:*

The mechanism of dehydrochlorination of ethylene chlorohydrin has been studied by comparing the relative rates of reaction in H_2O and D_2O [1]. The kinetics of the propylene chlorohydrin conversion to propylene oxide were determined with both NaOH and $Ca(OH)_2$ [2]. The relative rates of solvolysis of ethylene chlorohydrin, propylene chlorohydrin, and butylene chlorohydrin in water at 97 °C are 1.0 : 0.81 : 5.5 [3].

Hydroxyalkyl ethers may be prepared by reacting chlorohydrins with alcohols or phenols under basic conditions [4]. *Ethers of cellulose and starch* are manufactured by reacting these materials with various chlorohydrins. *Cationic starch* is made by reacting 3-chloro-2-hydroxypropyl trimethylammonium chloride with a starch slurry at pH 11 – 12 [5].

Chlorohydrins react with carboxylates in the presence of base to give *hydroxyalkyl esters.* On the other hand, *β-chloro esters* are formed by reaction with carboxylic acids under acid conditions [6] or from acid chlorides [7]. *Cyclic carbonates* may be produced by the reaction of a chlorohydrin with carbon dioxide in the presence of an amine [8].

A comparison of the rate of reaction of ethylene chlorohydrin with various *amines* gives the following order: *n*-amylamine > cyclohexylamine > aniline [9]. The reaction of ethylene chlorohydrin with ammonia gives

∗ In g/100 g.

monoethanolamine [10]. *Quaternary ammonium compounds* result from chlorohydrins and tertiary amines [11], [12].

Other chlorohydrin reactions include formation of *nitriles* from cyanides [13], *acetals* from aldehydes [14], *oxazolidinones* from cyanates [15], and the oxidation of ethylene chlorohydrin to *monochloroacetic acid* [16].

4. Production

In 1863, Carius [17] reported that chlorohydrins could be synthesized by reacting olefins with hypochlorous acid. As early as 1904, BASF began production of ethylene chlorohydrin by introducing ethylene and CO_2 into an aqueous solution of bleaching powder [18].

Ethylene Chlorohydrin. The reaction of chlorine and water (1) produces very little hypochlorous acid because of an unfavorable equilibrium, $K = 4.2 \times 10^{-4}$ [19].

$$Cl_2 + H_2O \rightleftharpoons HOCl + HCl \qquad (1)$$

Gomberg [20] reasoned that if the reaction between ethylene and hypochlorous acid (2) is significantly more rapid than the reaction of ethylene and chlorine to form dichloroethane (3), then as the ethylene is added to the aqueous system, chlorohydrin **1** should be produced preferentially.

(2)

1

(3)

He showed that with good stirring to minimize reaction (3) in the gas phase, little dichloroethane is produced until the chlorohydrin concentration reaches 6 – 8 %.

In reaction (1), the concentration of hypochlorous acid declines steadily as the HCl level increases. Significant quantities of dichloroethane are observed when the HCl concentration goes above 3 %. Because the solubility of dichloroethane in water is low (0.869 g/100 mL at 20 °C), it quickly forms a separate phase into which both chlorine and ethylene are preferentially dissolved to produce even more dichloroethane.

In a laboratory process study of the hypochlorination of ethylene, the effects of various reaction parameters were determined with both single-column and recycle-reactor arrangements [21]. Reaction temperatures of 35 – 50 °C and ca. 50 % excess of ethylene are preferred because these conditions allow much of the dichloroethane to be stripped from the reaction medium as it is formed.

For a continuous run with recycle at a chlorohydrin concentration of 6.4 %, a reactor temperature of 35 °C, an ethylene : chlorine ratio of 1.42, and a chlorine feed rate of 71 g/h, the average yield of ethylene chlorohydrin was 88.0 % with a dichloroethane yield of 10.1 %. Lowering the chlorine feed rate to 42 g/h raised the chlorohydrin yield slightly to 88.9 % and lowered the dichloroethane yield to 9.1 %.

For many years, ethylene chlorohydrin was manufactured on a large industrial scale as a *precursor to ethylene oxide.* This process has been almost completely supplanted by the direct oxidation of ethylene to ethylene oxide using silver catalysts (→ Ethylene Oxide). However, since other commercially important epoxides, such as propylene oxide and epichlorohydrin, cannot be made by direct oxidation of the parent olefin, chlorohydrin intermediates are still important in manufacturing these products. Although it is scarcely practiced today, a review of the ethylene chlorohydrin technology is valuable because of the close similarity of all of the chlorohydrin processes.

In a *typical industrial plant,* chlorine, ethylene, and water are concurrently passed upward through packed towers [22], [23]. These reactors are designed to minimize the contact between ethylene and gaseous chlorine and to provide adequate contact between the hydrocarbon feed and the liquid phase [24]. The feed lines are positioned a sufficient distance apart so that the chlorine can be completely dissolved in the water before the ethylene is introduced into the system. In some plants, there is a separate mixing column for chlorine and water followed by an ethylene reaction tower.

The reaction product is removed at the top of the tower as a 4.5 – 5.0 % solution of ethylene chlorohydrin, the yield of which may be as high

as 85 – 89 % of the ethylene converted. In addition to dichloroethane, small amounts of bis(2-chloroethyl) ether are formed as byproducts.

Propylene Chlorohydrin. The *hypochlorination of propene* gives two isomers:

The major side reactions are chlorine addition to give 1,2-dichloropropane [*78-87-5*], and formation of bis(2-chloro-1-methylethyl) ether [*108-60-1*]:

Propylene chlorohydrin reacts with a strong base, such as calcium hydroxide, to give *propylene oxide* [*75-56-9*] by dehydrochlorination (→ Propylene Oxide):

A typical flowchart for the production of propylene oxide through the chlorohydrin is shown in Figure 1 [25].

In the propylene chlorohydrin process, the separation of the feed points for chlorine and propene is even more critical than in the case with ethylene. The benefits of a recirculating-type, double-chamber reaction system have been described [26]. Chlorine was dissolved in a recycle stream of dilute aqueous propylene chlorohydrin together with makeup water. From this vessel, the effluent passed to a second chamber into which the propene was fed. This arrangement gave a propylene chlorohydrin yield of 87.5 % with 11.0 % dichloropropane and 1.5 % dichloroisopropyl ether. In contrast, a single-reactor system produced a 69.2 % chlorohydrin yield with 21.6 % dichloropropane and 9.2 % dichloroisopropyl ether.

Modern plants show propylene chlorohydrin yields of 87 – 90 % with 6 – 9 % dichloropropane. There are numerous patents that claim technology to boost chlorohydrin yields to 90 – 95 % [27–33].

A novel approach to hypochlorination involves the use of *tertiary alkyl hypochlorites* [34] and is based on the following chemistry:

The preferred alcohol in Reaction (4) is *tert*-butanol. The resulting *tert*-butyl hypochlorite has very slight water solubility and may be separated by phase. Thus, the reaction of the hypochlorite with propene and water (Eq. 5) occurs in an environment essentially free of chloride ions to reduce formation of the dichloride. A 95.8 mol % selectivity to propylene chlorohydrin is claimed [34]. A diagram of this process is shown in Figure 2 [35].

Glycerol Monochlorohydrins. *Hypochlorination of allyl alcohol* gives glycerol monochlorohydrins:

The reaction of allyl alcohol with chlorine and water at 50 – 60 °C is reported to give an 88 % yield of monochlorohydrins and 9 % dichlorohydrins [36].

Glycerol Dichlorohydrins. The *hypochlorination of allyl chloride* generates a mixture of the glycerol dichlorohydrins, 2,3-dichloro-1-propanol (**8**) and 1,3-dichloro-2-propanol (**7**), in about a 70 : 30 ratio.

Figure 1. Typical arrangement for propylene oxide via the chlorohydrin route

Reproduced with permission from [25].

Figure 2. Hypochlorite route to propylene oxide
Reproduced with permission from [35].

These may be subsequently saponified to *epichlorohydrin* [*106-89-8*]:

Because of the low water solubility of allyl chloride, it is essential to minimize formation of an organic phase, which leads to formation of the undesired byproduct 1,2,3-trichloropropane [24], [37]. This is commonly done by maintaining the allyl chloride as a fine dispersion by vigorous agitation in an aqueous system containing 10 – 50 volumes of water for each volume of allyl chloride [38–40]. Under such conditions, dichlorohydrin selectivities of 88 – 93 % are reported.

Another method of achieving a well-dispersed allyl chloride is by the use of a *surfactant* [41], [42]. Anionic or nonionic surfactants at a level of 0.2 – 0.5 wt % based on allyl chloride give reported dichlorohydrin yields of 93 – 95 % based on allyl chloride.

An alternative way of making dichlorohydrins is by *chlorination of allyl alcohol* [*107-18-6*], which may be produced by the hydrogenation of acrylaldehyde [*107-02-8*]. This route gives reported dichlorohydrin yields

of 94 – 98 % with a 2,3-dichloro-1-propanol yield of 88 – 97 % [43], [44].

Butene Chlorohydrins. Butylene chlorohydrin is prepared as a precursor to butene oxide. A laboratory study of the *hypochlorination of 2-butene* has been reported [45]. The dehydrochlorination of 3-chloro-2-butanol (**13**) with calcium hydroxide gave an 87 % yield of 2,3-butene oxide with 11 % glycol and 2 % methyl ethyl ketone [46].

Styrene Chlorohydrin. A laboratory preparation of styrene chlorohydrin (**19**) has been described [47]. Styrene was dispersed in water with a surfactant. Calcium hypochlorite solution was added to the vigorously stirred suspension through which carbon dioxide was bubbled. A 76 % yield of styrene chlorohydrin was obtained.

Long-Chain Chlorohydrins. Fatty acids containing unsaturation, such as oleic or elaidic acids, are converted to chlorohydrins as intermediates in making the epoxides or diols of these materials [48]. Long-chain olefins may be hypochlorinated with good selectivity (80 – 90 %) by using short reaction times, which result in low olefin conversion (5 – 25 %) [49].

Process Improvements. Some process improvements and new approaches for chlorohydrin production are the continuous production of glycerol dichlorohydrins [50], glycerol dichlorohydrins from allyl chloride [51], electrochemical chlorohydroxylation of olefins [52], 4-halo alcohols from ring cleavage of tetrahydrofuran [53], improved continuous production of aqueous propylene chlorohydrin solutions [54], high-yield continuous preparation of propylene chlorohydrin [55], ethylene chlorohydrin from ethanol [56], and chlorohydrins from immobilized halogenating enzymes [57], [58].

5. Environmental Protection

Unpublished data [59] for two of the chlorohydrin compounds are shown in Table 3 (there were no other data). Ethylene chlorohydrin is practically nontoxic to the fathead minnow according to a categorization system used by the U.S. Environmental Protection Agency. The two compounds in Table 3 are expected to be readily biodegradable.

Table 3. Environmental data on two chlorohydrins

	Biodegradation BOD/ThOD∗	Fathead minnow toxicity
Ethylene chlorohydrin	73 %	LC_{50}∗∗ > 100 mg/L
1,3-Butene chlorohydrin	67 %	no data

∗ BOD/ThOD = biochemical oxygen demand/theoretical oxygen demand.
∗∗ LC_{50} = lethal concentration to 50 % of the test organisms in a specified time.

6. Chemical Analysis

In addition to the conventional wet quantitative method, other modern spectroscopic analyses have been used, including Raman spectroscopy [60] and gas chromatographic analysis [61]. Potentiometric determination of propylene chlorohydrins [62] and enzymatic determination of ethylene chlorohydrin [63] were also reported.

7. Storage and Transportation

Chlorohydrins generally can be stored in acid-resistant tanks with a small or low-pressure rating. Titanium metal is resistant to corrosion by most chlorohydrins [64]. Potentiometric study of the corrosion of chlorohydrins up to 120 °C on titanium and steel has been reported [65]. Chlorohydrins in general are not classified as hazardous materials by the U.S. Department of Transportation. They can be shipped in acid tank railroad cars or trucks [64].

8. Uses

Chlorohydrins find their greatest utility as intermediates in the manufacture of epoxides, especially propylene oxide and epichlorohydrin. For reviews of these processes, see the following references: [25], [66–68], → Epoxides, → Ethylene Oxide, → Propylene Oxide.

Adducts of ethylene chlorohydrin with tungsten or molybdenum halides plus an organoaluminum compound have been patented as catalysts for olefin metathesis and cycloalkene ring-opening polymerization [69–72].

Chlorohydrins have also been used in the following ways:

– intermediate for plasticizers [73]
– wet strengthening agent for paper [74], [75]
– etherizing agent of phenolic resin to produce a high-temperature heavy-metal chelating compound [76]
– preservation of biological fluids and solutions [77]
– treatment of sulfonyl halides and dimethylamine aromatic compounds for fluorescent whitening agents and photosensitizers [78]
– raw material for lubricating oil intermediates and additives [79], [80]
– reaction with 1,3-bis(dimethylamino)-2-propanol to form a flocculant [81]
– production of low molecular mass epoxy resins [82]
– raw material for flame retardants for polymers [83]
– soil-resistant yarn-treating agent [84], [85]
– hardener for polyurethane elastomers [86]

Pharmaceutical and agricultural chemical applications have been explored. Chlorohydrins are used as base chemicals for various drugs and chemicals, such as the following:

– carbazole derivative for treatment of anxiety [87]
– pharmaceutically acceptable salts [88]
– quaternary ammonium polymeric antimicrobial agents [89]
– substituted nitrodiphenyl ethers [90]
– phenoxyalkanol antirhinovirus agents [91]
– quaternary salts of promethazine bronchoconstriction releasing agent [92]
– substituted oxobenzothiazolines plant growth regulators [93]
– phenyl urea derivative herbicides [94]

9. Toxicology and Occupational Health

Of the various chlorohydrins, ethylene chlorohydrin and α-chlorohydrin have been the most extensively studied, the former because it is a residue produced when poly(vinyl chloride) plastics are sterilized with ethylene oxide.

Ethylene Chlorohydrin. The American Conference of Governmental Industrial Hygienists TLV-TWA is 1 ppm (3 mg/m^3) as a ceiling limit with a skin notation, which indicates that the dermal route is significant. The MAK values are the same. The Occupational Safety and Health Act PEL is 5 ppm with a skin notation.

Ethylene chlorohydrin is moderate to high in acute oral toxicity with an LD_{50} of 89 mg/kg for rats [95]. It is also high in dermal toxicity as its dermal LD_{50} is 84 mg/kg in rabbits [95], a value that places ethylene chlorohydrin into the class B poison category for the U.S. Department of Transportation. A volume of ca. 5 cm^3 could be lethal to the average adult male (70 kg) if it contacts the skin and is not washed off immediately. Ethylene chlorohydrin is not particularly irritating to the skin or eyes; however, it causes slight to moderate irritation, depending on the circumstances. Excessive vapor concentration of ethylene chlorohydrin is attainable, and a single exposure at elevated concentration may cause death. One fatality due to a 2-h inhalation of ethylene chlorohydrin vapor at ca. 1 mg/L (ca. 306 ppm) has been reported [96]. Two fatal and several nonfatal cases of intoxication by ethylene chlorohydrin were investigated [97]. The average concentration in the nonfatal cases was 18 ppm. Nonfatal cases showed signs of circulatory shock, lack of coordination, repeated vomiting, epigastric pain, headache, heavy urine output, cough, and skin reddening. In another case report [98], autopsy findings showed damage to the lungs, liver, kidneys, brain, and other organs.

Ethylene chlorohydrin is considered to be *noncarcinogenic* on the basis of a test in which it was given to rats by subcutaneous injection for 1 year with a 6-month hold [99], and also on the basis of a skin painting test in rats and mice [100]. Ethylene chlorohydrin did not cause birth defects in rabbits when administered intravenously in doses up to 36 mg kg^{-1} d^{-1} during the period of organogenesis. When administered to mice at higher doses, 120 mg kg^{-1} d^{-1} caused a significant increase in the number of malformed fetuses and resorptions when accompanied by maternal toxicity [101]. There have

been no studies of ethylene chlorohydrin and its effect on male or female reproductive systems.

In the *Ames bacterial mutagenicity test,* ethylene chlorohydrin is sometimes positive and sometimes negative, with some of the positives only occurring after alteration by tissue homogenates (presumably creating metabolites that are known to be active) [102–104]. Ethylene chlorohydrin is also weakly and sporadically mutagenic when tested in animal cell systems. It is reported to have induced chromosome aberrations in rat bone marrow cells [105], but it did not produce a significant increase in the number of translocation heterozygotes (heritable translocation) when administered to male mice at 30 – 60 mg kg^{-1} d^{-1} for 5 weeks [106]. It was also negative in tests with fruit flies [107].

The toxicity of ethylene chlorohydrin (and presumably other activity, such as mutagenicity) is believed to be due to its *conversion to chloroacetaldehyde* in vivo. Chloroacetaldehyde and chloroacetic acid, which are metabolic intermediates, are to a great degree conjugated and inactivated by reaction with glutathione. Thus, when ethylene chlorohydrin levels are highly elevated, glutathione is depleted and chloroacetaldehyde cannot be detoxified. When chloroacetaldehyde levels at intracellular sites are elevated, other cell components are alkylated, damage to major organs occurs, and toxic symptoms are produced [108], [109].

α-Chlorohydrin. This member of the chlorohydrin series has also been extensively studied for its toxicological effects. Its chronic toxicological profile differs greatly from that of ethylene chlorohydrin. There is apparently no industrial hygiene exposure guide for α-chlorohydrin. α-Chlorohydrin is also high in acute oral toxicity, with an LD_{50} of 55 mg/kg in rats [110], and is apparently also high in dermal toxicity. The rabbits placed on skin irritation tests all died with one small application, and one was examined and found to have "widespread liver damage" [59]. The material was essentially nonirritating to skin. The vast majority of toxicological information on α-chlorohydrin is from investigation of its effect on male reproduction. This antifertility effect, which α-chlorohydrin has on the male, was demonstrated in 1969 and 1970 [111], [112], and has been shown to be predictable for rats by oral, injection, and inhalation routes.

Because of the potential utility of α-chlorohydrin as a *male contraceptive*, its mechanism of action has been thoroughly studied. Only the S isomer has been determined to possess antifertility activity; it has none of the detrimental effect on the kidneys associated with the R isomer [113]. α-Chlorohydrin and epichlorohydrin produce similar effects on the male reproductive system of the rat, i.e., epididymal sperm granulomas, spermatocoeles, and an increase in the number of morphologically abnormal spermatozoa [114]. There is evidence that the profile of action may be slightly different in primates [115].

Like ethylene chlorohydrin, α-chlorohydrin is *weakly mutagenic* in some tests [116], but α-chlorohydrin may be a direct-acting mutagen.

α-Chlorohydrin was tested for *carcinogenicity* and gave ambiguous results in an oral test using rats. Toxicity (testicular effects) was noted at the two dose levels used; and although not statistically significant, there were tumors of the parathyroid that were in question in this test [117]. In mice, α-chlorohydrin produced no carcinogenic effects via skin painting and subcutaneous injection [118].

Other Chlorohydrins. Data for other chlorohydrins are primarily of the acute variety. *1-Chloro-2-propanol* is moderate in acute oral toxicity with an LD_{50} of 100 – 300 mg/kg in rats and moderate in acute dermal toxicity with an LD_{50} of ca. 500 mg/kg in rabbits. It is only slightly irritating to the skin, and slightly to moderately irritating to the eyes [59]. The Dow Industrial Hygiene Guide is 3 ppm as a ceiling limit with a skin notation and is based on the following: (1) acute data which showed that rats were able to survive at most a 15-min exposure to a saturated atmosphere (nominal concentration 13 000 ppm) [59]; (2) a 22-week intubation study in rats, which showed only slight liver effects (organ weight increase) at 25 mg kg^{-1} d^{-1} [119]; and (3) an inhalation test in rats, in which 14 exposures to 30 ppm caused no adverse effects, but higher concentrations caused lung congestion and lethargy [120].

A *mixture of 2-chloro-1-propanol and 1-chloro-2-propanol* was mutagenic in the Ames strains TA1535 and TA100 with and without

metabolic activation but with enhanced activity after activation. The mixture was also mutagenic in a mouse lymphoma assay and in a rat cytogenetic test [121]. Such a mixture was also fed to rats and dogs for 90 days at doses ranging from 1 to 50 mg kg^{-1} d^{-1} [122]. No significant effects occurred in rats at any dose nor in dogs at 1 or 7 mg kg^{-1} d^{-1}. Only reduced food consumption, reduced body weight, and increased relative liver weight occurred at 50 mg kg^{-1} d^{-1} in dogs.

1,3-Dichloro-2-propanol is moderate in acute oral toxicity with an LD_{50} of between 126 and 252 mg/kg in rats, is moderate in acute dermal toxicity with an LD_{50} of between 500 and 1000 mg/kg in rabbits, and is moderately irritating to the eyes and moderately to severely irritating to the skin [59]. In inhalation tests, a 4-h exposure to 1000 ppm was lethal to five of five rats, while no rats died as a result of inhaling 1000 ppm for 2 h. Rats were able to survive a 4-h exposure at 300 ppm but not 7 h at 300 ppm [59]. This chlorohydrin was mutagenic toward Ames tester strains TA100 [116] and TA1535 [123] and in other such Ames tests.

2,3-Dichloro-1-propanol is moderate to high in acute oral toxicity with an LD_{50} of 90 mg/kg in rats, moderate in acute dermal toxicity with an LD_{50} of 0.2 mL/kg in rabbits, and also moderately irritating to the eyes and skin [124]. It is mutagenic toward Ames strain TA1535 [123] and in other Ames tests.

There are no toxicity data for either 3-chloro-2-butanol or 2-chloro-1-butanol (this should not be confused with chlorobutanol, which is the anesthetic having the full name trichloro-*tert*-butyl alcohol). There are also no data for the other glycerol monochlorohydrin, 2-chloro-1,3-propanediol.

Acute data indicate that *styrene chlorohydrin* is low in acute oral toxicity with an LD_{50} between 500 and 2000 mg/kg in rats [59], but there is no dermal LD_{50} available. Styrene chlorohydrin is quite irritating to the eyes and skin. Inhalation presents no hazard from exposure at room temperature; however, if the material is heated, the vapors thus generated may cause irritation and possibly organ effects (kidney and liver) [59].

1. Introduction

In chlorophenols the aromatic ring of phenol is substituted with one to five chlorine atoms. Laurent discovered this group of compounds when he chlorinated coal tar in 1836 [1], [2].

Chlorophenols are industrially important because of their broad spectrum of antimicrobial properties and their uses as fungicides, herbicides, insecticides, ovicides, and algicides. A mixture of tetrachlorophenols and pentachlorophenol, either as such or as salts or esters, finds widespread use as a preservative for wood, glue, paint, vegetable fibers, and leather. In addition, chlorophenols are widely used as intermediates in chemical syntheses.

2. Physical Properties

Important characteristics and physical properties of chlorophenols are shown in Tables 1 and 2. With the exception of 2-chlorophenol, these compounds are solid at ambient temperature; they all have strong characteristic odors. Several of them sublime readily. They can be steam-distilled. The chlorophenols are only slightly soluble in water, but highly soluble in alcohols. They impart a strongly disagreeable taste to drinking water.

3. Chemical Properties

Chlorophenols are versatile intermediates in chemical syntheses because both the hydroxyl group and the aromatic ring can react by both electrophilic and nucleophilic substitution. They are readily oxidized.

3.1. Reactions of the Hydroxyl Group

Chlorophenols are more acidic than phenol and readily form salts with alkali and alkaline-earth hydroxides or carbonates or with amines. These salts are stable and soluble in water.

Chlorophenols readily form esters of both organic and mineral acids [3–5]. Esters such as chlorophenyl phosphates, carbamates [6], [7], chloroformates [8], carbonates, and laurates are widely used. Pentachlorophenyl 2-ethylhexanoate is used as a textile preservative.

Chlorophenols are also readily O-alkylated, and ethers derived from aliphatic, aromatic, and heterocyclic reagents comprise a broad class of industrial products [9], [10]. One of

the most widely known is 2,4-dichlorophenoxyacetic acid [*95-75-7*] (2,4-D), which is still used as a selective herbicide for broadleaf plants [11–13] (→ Chlorophenoxyalkanoic Acids).

3.2. Electrophilic Substitution of the Aromatic Ring

Electrophilic substitution is favored by the presence of chlorine atoms on the aromatic nucleus; thus, most chlorophenols partake in the standard reactions, such as alkylation, acylation, nitration, sulfonation, halogenation, [14–16], carboxylation, and condensation with aldehydes, e.g., formaldehyde, chloral, glyoxylic acid [17–19].

3.3. Nucleophilic Substitution of the Aromatic Ring

Nucleophilic substitution for one or more of the chlorine atoms, although disfavored by the presence of the other chlorine atoms, is nevertheless used widely.

The hydrolyses of 2-chlorophenol and 4-chlorophenol were used at one time to obtain pyrocatechol [*120-80-9*] and hydroquinone [*123-31-9*], respectively. The ammonolysis of 2-chlorophenol or 4-chlorophenol produces 2-aminophenol or 4-aminophenol, respectively. This type of reaction is used primarily to prepare various substituted diphenyl ethers, which serve as efficient herbicides [20–22].

Chlorophenols can be converted into poly-chlorinated alicyclic ketones such as "hexachlorophenol" [*599-52-0*] by reac-

tion of chlorine in aqueous acetic acid. "Hexachlorophenol" has pesticidal properties and is hydrolyzed to chloranil [*2435-53-2*] in the presence of an acidic catalyst such as sulfuric acid.

3.4. Oxidation Reactions

Like other phenols, chlorophenols can be oxidized; air oxidation forms chloroquinones, whereas oxidation with hydrogen peroxide leads to the corresponding chlorinated diphenol. Oxidation by a peroxide such as perpropionic acid in benzene at 80 °C yields chlorodiphenols (85 % yield) [23]:

4. Production

There are two types of chlorophenols: (1) those with one to three chlorine atoms but none in a meta (3 or 5) position relative to OH and those which have four or five chlorine atoms, and (2) those with one to three chlorine atoms, at least one being in a meta position relative to OH.

4.1. Mono-, Di-, and Trichlorophenols with no Chlorine in a Meta Position; Tetrachlorophenols; and Pentachlorophenol

The mono-, di-, and trichlorophenols which have no chlorine atom in the meta (3 or 5) position relative to OH are 2-chlorophenol, 4-chlorophenol, 2,4-dichlorophenol, 2,6-dichlorophenol, and 2,4,6-trichlorophenol. The tetrachlorophenols and pentachlorophenol are also included with this type. These compounds are obtained by the direct chlorination of phenol.

The chlorination of melted phenol [*108-95-2*] using chlorine gas [*7782-50-5*] yields a mixture of ortho and para monochlorophenols with an *o*/*p* ratio of ca. 0.54 (35/65), which is scarcely dependent on temperature. The distribution between the two isomers depends especially on the nature of the chlorination reagent and the characteristics of the reaction medium. The formation of 2-chlorophenol is favored by an aprotic nonpolar solvent medium, such as hexane, carbon tetrachloride, or dichloroethane. The *o*/*p* ratio is also higher for reactions with a low concentration of phenol and a high temperature [24]. The chlorination of a 5 % solution of phenol in perchloroethylene at 110 °C in the presence of 0.01 wt % diisopropylamine [*108-18-9*] gives a very high *o*/*p* ratio, ca. 15 [25]. Chlorinations using aqueous sodium hypochlorite [*7681-52-9*] at pH 10, *tert*-butyl hypochlorite [*507-40-4*] and alkali phenolates dispersed in an anhydrous medium [26], or chlorine in acetic acid in the presence of acetic anhydride [*108-24-7*] also favor the formation of 2-chlorophenol [27].

The formation of 4-chlorophenol is favored by chlorination in a polar medium, such as acetonitrile, nitrobenzene, or ether [28–31]. Substitution in the para position is also strongly favored by the use of sulfuryl chloride [*7791-25-5*] as a chlorinating agent ($o/p = 0.35$) [28], [31]. Certain organic sulfides, e.g., diphenyl sulfide [*139-66-2*], activate chlorination and favor substitution at the para position [32]. Chlorination using copper(II) chloride in aqueous hydrochloric acid in the presence of oxygen leads to 4-chlorophenol (almost 100 %) [33].

Mono-, di-, and trichlorophenols are made industrially by chlorination of phenol with chlorine gas in a melt in cast-iron reactors. The isomer distribution in the product may be adjusted to market demands by the chlorination level and by recycling various intermediates. The yield, based on chlorine and phenol, is greater than 95 %.

Tetrachlorophenols and pentachlorophenol are produced batchwise in nickel reactors by the chlorination of less halogenated chlorophenols in the presence of aluminum trichloride [*7446-70-0*] or iron trichloride [*7705-08-0*].

4.2. Mono-, Di-, and Trichlorophenols with Chlorine in a Meta Position

The mono-, di-, or trihalogenated phenols having at least one chlorine atom in a meta position are 3-chlorophenol, 2,3-dichlorophenol, 2,5-dichlorophenol, 3,4-dichlorophenol, 3,5-dichlorophenol, 2,3,4-trichlorophenol, 3,4,5-trichlorophenol, and 2,3,6-trichlorophenol.

These compounds cannot be obtained by the chlorination of phenol, but must be made by other types of reactions, such as hydrolysis, sulfonation, hydrodechlorination, hydroxylation, and alkylation.

Hydrolysis of chlorobenzenes can be carried out in alkaline aqueous media, with or without the presence of copper salts [34]. It can be done in the vapor phase at 250 – 400 °C on phosphates [35] or on silica at 500 – 550 °C [36]. Hydrolysis is most frequently carried out in the presence of methanolic sodium or potassium at 150 – 200 °C and 1.0 – 3.0 MPa [37], [38].

Sulfonation – Desulfonation. Sulfonation of chlorobenzenes followed by the desulfonation of chlorobenzenesulfonic acids can be used to produce numerous chlorophenols [39–44]. The chlorobenzenes are sulfonated by using 15 – 20 % oleum at 60 – 80 °C. The subsequent desulfonation is usually carried out by using 15 – 25 % aqueous sodium hydroxide solution at 180 –220 °C and 1.5 – 3.0 MPa.

Sandmeyer Reaction. *m*-Chlorophenols can also be made by diazotization of the corresponding chloroanilines that have been obtained either by nitration of chlorobenzenes followed by hydrogenation or by chlorination of nitrobenzenes [42].

Hydrodechlorination. Hydrodechlorination of polychlorophenols produces 3-chlorophenols. This reaction has long been carried out either in the vapor phase at 300 – 350 °C on an alumina catalyst [45] or in the liquid phase at 150 – 250 °C and 15.0 – 20.0 MPa, usually in the presence of sulfur [46], [47]. More recently, *catalytic hydrodechlorination* of polychlorophenols in organic or aqueous media with a palladium catalyst was used to obtain 3-chlorophenol and 3,5-dichlorophenol [48]. Hydrodechlorination of polychlorophenols with hydriodic acid in an aqueous or organic medium has also been reported [49].

Hydroxylation. Hydroxylation of chlorobenzenes gives a mixture of 55 wt % 4-chlorophenol, 30 – 35 wt % 2-chlorophenol, and 15 wt % 3-chlorophenol [50].

Hock Phenol Synthesis. The propylene alkylation of a chlorobenzene followed by oxidation and decomposition of the hydroperoxide in an acid medium produces the corresponding chlorophenol [46], [51].

The physical properties of the principal commercial chlorophenols are given in Table 2.

5. Analysis

The acidity of the phenol function in chlorophenols increases with increasing chlorination of the benzene ring. Potentiometric analysis with either soda in an aqueous medium or an amine in an organic medium is, therefore, suitable. Good sensitivity is obtained by using cyclohexylamine in ethylene glycol monoethyl ether as solvent [53], [54].

Chlorophenols are difficult to separate by gas chromatography because of their high acidity. However, the light homologues can be separated by using an acidic solid support in a glass column. The heavy homologues can be separated only after the phenol function is blocked by means of methylation, acetylation, silylation, or phthalation. Traces of chlorophenols may be determined as their trifluoroacetylated derivatives by gas chromatography with electron capture detection (limit of detection ca. 20 mg/L) [52], [54].

All phenols are correctly separated by reverse-phase HPLC on a silica column grafted with C_{18} species. Grafts of the propylamino type enable separations based on the degree of chlorination (the retention time depends on the pK_a). UV (280 nm) detection is normally used; amperometric detection is 100 times more sensitive [55–58].

IR spectrometry can distinguish between the different isomers, which absorb in the region 1600 – 400 cm^{-1} [59]. Proton NMR spectrometry can identify most of the different chlorophenols by the chemical shift and the coupling of their aromatic protons. Pentachlorophenol can be identified after the phenol group has been complexed with hexamethylphosphoric triamide [*680-31-9*]. Carbon-13 NMR is less sensitive than proton NMR, but it can provide even more useful information [60].

The individual chlorophenols can be identified and determined with great sensitivity by means of gas chromatography followed by chemical ionization mass spectrometry. The chlorophenols are first converted to their pentafluorobenzyl ether or pentafluorobenzoic ester derivatives. The analysis is then carried out on these species because of their higher electronegativity [61].

Thermal or chemical degradation of chlorophenols can produce substances that are deleterious to the environment. Certain polychlorodibenzoparadioxins, polychlorodibenzofurans, and polychlorophenoxyphenols are examples. These substances can be determined by HPLC with UV detector at a sensitivity of ca. 1 mg/kg [50], [52]. Determinations at the µg/kg level require that the sample be pretreated to remove the major portion of the chemical interferences. The sample is first extracted from an alkaline medium with hexane and then separated on an alumina liquid chromatography column.

The chosen compounds can then be collected into homologous groups [62]. The final determination is made by using GC with electron capture detection or by combined gas chromatography and mass spectrometry. The limit of detection for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin [*1746-01-6*] (TCDD) is less than <1 µg/kg [52].

6. Quality Specifications

The minimum assay for commercial chlorophenols is 98.5 wt %. More often than not, it is >99 wt % and at times even 99.5 wt %. The APHA color number is always <100. The principal impurities are other isomers of the chlorophenol or chlorophenols with more or fewer chlorine atoms. In the majority of cases, the 2,4,5-trichlorophenol content is <20 mg/kg. The absence of chlorobenzoparadioxins, chlorobenzofuran, and most often chlorobenzenes should be noted.

Polychlorophenoxyphenols are the major impurity (up to several percent) in the heavy chlorophenols, which are marketed as mixtures of tetrachlorophenols and pentachlorophenol. Trace quantities of chlorobenzoparadioxins and chlorobenzofuran are also found. The highly toxic compound 2,3,7,8-tetrachlorodibenzo-*p*-dioxin has never been detected in products made by chlorination [52]. The sodium salts of the heavy chlorophenols contain the same impurities as the parent compounds.

7. Economic Aspects

The world market, excluding the Comecon countries and China, is fairly stable and is ca. 100 000 t/a.

The production of heavy chlorophenols is 25 – 30 kt/a. Of this 16 – 20 kt/a is produced in the United States (Vulcan, Reichhold), 8 – 10 kt/a in Western Europe (Rhône-Poulenc, Dynamit Nobel), and 2 kt/a elsewhere in the West.

Production of light chlorophenols is ca. 60 kt/a. Of this, 18 – 20 kt/a is made in the United States (Dow) and 30 kt/a in Western Europe (Rhône-Poulenc, BASF, Coalite, Bayer, Chemie Linz, Esbjerg, KVK).

8. Uses

Chlorophenols are used as agricultural chemicals, pharmaceuticals, biocides, and dyes.

Agricultural Chemicals. The preparation of agricultural chemicals consumes 80 – 90 % of chlorophenol production. The annual consumption of the herbicides 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4-dichlorophenoxy-4-butyric acid is 30 – 40 kt. Hoelon (Hoechst), Modown (Mobil), Ronstar (Rhône-Poulenc), and TOK E-25 (Rohm and Haas) are among the major *herbicides.* Curacron (Ciba Geigy) exemplifies the *insecticides* made from chlorophenols. Among the *fungicides* are Bayleton (Bayer), MO (Mitsui Toatsu Chemicals), and Procloraz or Sportak (Boots).

Pharmaceuticals. Pharmaceuticals derived from chlorophenols include clofibrate, ethyl 2-(4-chlorophenoxy)-2-methylpropionate (ICI), used in the treatment for high serum cholesterol, and Mervan or Aldofene, an antiinflammatory and analgesic drug (Continental Pharma).

Biocides. Biocides that are based on chlorophenols include the molluscicide Bayluscide (Bayer) and the bactericide Santophen or Chlorophen (Monsanto). Pentachlorophenol is also used to make wood and cellulose preservatives, esters for the textile and leather industries, paints, varnishes, and organic adhesives.

The sodium salt of pentachlorophenol is an active, water-soluble material. It is used as a preservative for such organic materials as freshly sawn wood (against blue rot), paints, adhesives, textiles, leather, and furs.

Dyes. Chlorophenols are used in the synthesis of anthraquinone dyes (→ Anthraquinone Dyes and Intermediates). Quinizarin, 1,4-dihydroxy-9,10-anthracenedione [*81-64-1*], is the most important example.

9. Storage and Transportation

The production, storage, transportation, and use of chlorophenols are subject to regulations and stipulations that depend on the products and on the countries concerned. Within the EEC, directive 67/548 governs classification, packing, and labeling; directive "131" 76/464 covers discharges from production plants into aquatic media; directives 77/728 and 78/631 regulate the relevant paints and pesticides, respectively.

Transportation of chlorophenols is governed by international regulations such as IMDG Code (sea), IATA-DGR (air), RID (rail), and ADR (road).

10. Environmental Considerations

Chlorophenols are hazardous to the environment and have been the subject of numerous ecological surveys of fauna and flora in aquatic, terrestrial, and aerial environments [63].

10.1. Toxicity to Fauna and Flora

Microorganisms. All chlorophenols possess bactericidal activities that increase with the degree of chlorination and attain a maximum for the trichlorophenols. Their metabolic effects include enzyme inhibitions of oxidative phosphorylation and the synthesis of adenosine triphosphate. Chlorophenols are highly toxic to algae. Trichlorophenols are at least 100 times more toxic than dichlorophenols, and pentachlorophenol is used as an algicide.

Plants. Chlorophenols possess a phytotoxicity that increases with the degree of chlorination. The absorption of chlorophenols by plants depends on the solubility of the product and pH of the environment. Terrestrial and aquatic plants can in certain cases absorb, transform, and eliminate chlorophenols without harm, but most often these plants are very sensitive to the phytotoxicity of chlorophenols.

Aquatic Organisms. Fish and other aquatic organisms absorb chlorophenols through their gills, gastrointestinal tract, or skin. Measurements over 2 – 4 d show that acute toxicity for invertebrates, crustacea, and freshwater and seawater fish increases with the level of chlorination. For mono-, di-, and trichlorophenols, the 2 – 4 d LC_{50} is 0.6 – 10.3 mg/L, depending on

the species. For pentachlorophenol, it is 0.03 – 0.6 mg/L, except for certain resistant invertebrates that can survive concentrations of 5 – 10 mg/L.

Chlorophenols also have a long-term toxic effect at low concentrations. 2,4-Dichlorophenol and 2,4,6-trichlorophenol at concentrations of 6.2 – 10.3 mg/L affect the fertilization of sea urchin eggs, and pentachlorophenol causes renal and hepatic lesions in fish. The EPA recommends that the maximum average pentachlorophenol concentration in surface waters not exceed 0.055 mg/L. For 2,4-dichlorophenol and 2-chlorophenol, the EPA set the maximum concentrations at 2.020 and 4.380 mg/L, respectively [64]. This limitation, based on toxicity, is strengthened by the fact that chlorophenols bioaccumulate to only a small extent [65], [66].

10.2. Persistence in the Environment

Aquatic Environment. Chlorophenols may be present in the aquatic environment in many forms. They may be dissolved in free or complexed form, adsorbed on suspended inert solid or biological materials or benthic sediments, or carried in biological tissues. They are removed by biodegradation, photodecomposition, volatilization to the atmosphere, and adsorption.

*Biodegradation*is the principal means by which chlorophenols are removed. It must be induced because the antimicrobial activities of these products require that the bacteria adapt. Biodegradation is rapid when adapted microorganisms are already present, but pentachlorophenol is more difficult to biodegrade than the other chlorophenols.

Chlorophenols *photodecompose* when exposed to UV light, such as sunlight on the water surface.

*Volatilization*transfers the chlorophenol from the water to the air but does not otherwise affect it. The *adsorption* of chlorophenols on suspended or benthic materials also plays a role in the amount of chlorophenols in water. Light chlorophenols are fixed to only a small extent, but pentachlorophenol adsorbs very strongly on certain types of particles when conditions are suitable.

Terrestrial Environment. The persistence of chlorophenols in the soil depends on their adsorption – desorption characteristics. Only the adsorption of pentachlorophenol has been studied in depth. It attaches very strongly to earth and is not easily washed away by rain [67].

Atmosphere. The presence of chlorophenols in the atmosphere has been inferred from the detection of minute quantities of pentachlorophenol in rainwater and snow.

11. Toxicology

The toxicity of chlorophenols to animals depends upon the degree of chlorination, the positions of the chlorine atoms, and the purity of the sample. The LD_{50} values for rats are given in Table 3 [30]. In rats and rabbits, 50 % of the administered dose of pentachlorophenol is eliminated within 24 h. In mice, 70 – 85 % of the dose is eliminated within 4 d. The elimination of tetrachlorophenols is comparable to that of pentachlorophenol [63].

Table 3. Lethal doses (LD_{50}) of chlorophenols for rats

Chlorophenol	LD_{50}, mg/kg	
	oral	percutaneous
2-Chlorophenol	670	950
3-Chlorophenol	570	1030
4-Chlorophenol	261	1390
2,4-Dichlorophenol	580	1730
2,4,5-Trichlorophenol	820	2260
2,4,5-Trichlorophenol, sodium salt	1620	
2,4,6-Trichlorophenol	820	
2,3,4,6-Tetrachlorophenol	140	210
Pentachlorophenol	50	100
Pentachlorophenol, sodium salt	210	72

Toxic doses of chlorophenols cause convulsions, as well as other symptoms [63]. Trembling and clonic convulsions can be induced by tactile or auditory stimulation. Agitation and polypnea are observed before muscular weakness; dyspnea and coma occur and finally death [37], [66]. The toxic effects of pentachlorophenol and the tetrachlorophenols are due to the inhibition of oxidative phosphorylation.

After repeated administration, toxic doses of chlorophenols cause mainly hepatic and renal lesions. The no-effect doses were ca. 100 mg/kg for 2,4-dichlorophenol and 2,4,6-trichlorophenol and 1 – 5 mg/kg for pentachlorophenol [63].

Investigations of the elimination and metabolism of chlorophenols have been inconclusive. Dogs excrete 2-chlorophenol in the urine as both the free and conjugate forms (87 %). However, with rabbits 2-chlorophenol is detected after the administration of chlorobenzene. 2,4-Dichlorophenol, 2,4,6-trichlorophenol, and traces of 2,4,5-trichlorophenol are found in their free and conjugate forms, following the administration of β- or γ-hexachlorocyclohexane to mice.

2,4,5-Trichlorophenol and its conjugate forms are found in the urine following the administration of 2,4,5-trichlorophenoxy-4′-butyric acid to mice; 2,3,4,5-, 2,3,4,6-, and 2,3,5,6-tetrachlorophenols, free and in their conjugate forms, are detected after the administration of pentachlorophenol [61].

Chronic effects of human exposure to low doses of chlorophenol have not been reported, but toxic doses of pentachlorophenol cause severe pathological modifications in the gastrointestinal tract, lungs, spleen, liver, kidneys, and cardiovascular system. Low levels of pentachlorophenol have been found in the urine, blood, and body fat of exposed and unexposed persons, but no explanation for their presence is available. Certain chlorophenols cause dermatoses such as photoallergic contact dermatitis, papulofollicular lesions, comedones, and sebaceous cysts [40], [41], [63], [68].

1. Introduction

Research on chlorinated phenoxy compounds during World War II led to the discovery of the selective *herbicidal action* of 2,4-dichlorophenoxyacetic acid (2,4-D) for control of broadleaf weeds in grasses and related crops, such as cereal grains, rice, and sugarcane. Use patents issued before 1950 included several in the United States assigned to American Chemical Paint Co. (Amchem, now Union Carbide) and Dow Chemical [1].

Although all patents have expired and many new plant growth regulator type weedkillers have been developed, phenoxy compounds still comprise a large sector of the worldwide herbicide market. The estimated total *capacity* for manufacture of chlorophenoxyalkanoic acids and derivatives approached 2×10^5 t in 1982, with a value of about \$ 1.75/kg (\$ 0.80/lb.). Total production decreased about 10 % worldwide in 1983 because of weak prices and lower demand.

The *principal chlorophenoxyalkanoic acids used as herbicides* are listed in Table 1. They are formulated as water-soluble salts and oil-soluble or emulsifiable esters. Major products, in terms of volume, are 2,4-D and MCPA followed by mecoprop and dichlorprop. Most production of 2,4,5-T and fenoprop has been discontinued because of the high toxicity of the dioxin contaminant formed during manufacture of the 2,4,5-trichlorophenol intermediate used for making these herbicides.

Detailed information on individual chlorophenoxyalkanoic acids and their derivatives can be found in herbicide manuals and handbooks [1–4] and in extensive reviews published since 1970 [5–18].

2. Production

Pokorny Process. Most technical phenoxy acids are produced by using the simple reaction first described in 1941 by POKORNY [19] for synthesis of 2,4-D and 2,4,5-T. The appropriate chlorophenol is reacted with a chloroalkanoic acid under alkaline conditions at about 100 °C in an aqueous medium or in an organic solvent, such as toluene, xylene, or chlorobenzene:

where R^1 is CH_3 or Cl, R^2 is H or Cl, R^3 is H or CH_3, $R^4R^5R^6N$ is an alkylamine, R^7OH is an alcohol, and MOH is an alkali metal base. The resultant salt is hydrolyzed to the free acid, which is purified by recrystallization from an organic solvent or by steam distillation. Chlorophenoxy acids prepared from 2-chloropropionic acid contain an asymmetric carbon atom and are isolated as racemic mixtures. A schematic diagram of the Pokorny process used to produce 2,4-D, its salts, and its esters is shown in Figure 1.

Various methods for synthesis of chlorophenoxyalkanoic acids, esters, and salts have been reviewed [10, pp. 107 – 123]. The nature and quantity of byproducts depend largely on the purity of the starting chlorophenols (→ Chlorophenols). For example, the 2,4-dichlorophenol used for making 2,4-D, dichlorprop, and 2,4-DB is pre-

Table 1. Chlorophenoxyalkanoic acids used as herbicides ∗

Common name	Chemical name (IUPAC)	CAS registry number	Formula	M_r
2,4-D	(2,4-dichlorophenoxy)acetic acid	[*94-75-7*]	$C_8H_6Cl_2O_3$	221.04
2,4-DB	4-(2,4-dichlorophenoxy)butyric acid	[*94-82-6*]	$C_{10}H_{10}Cl_2O_3$	249.09
Dichlorprop	2-(2,4-dichlorophenoxy)propionic acid	[*120-36-5*]	$C_9H_8Cl_2O_3$	235.05
MCPA ∗∗	(4-chloro-o-tolyloxy)acetic acid	[*94-74-6*]	$C_9H_9ClO_3$	200.63
MCPB ∗∗	4-(4-chloro-o-tolyloxy)butyric acid	[*94-81-5*]	$C_{11}H_{13}ClO_3$	228.68
Mecoprop ∗∗	2-(4-chloro-o-tolyloxy)propionic acid	[*93-65-2*]	$C_{10}H_{11}ClO_3$	214.66
2,4,5-T	(2,4,5-trichlorophenoxy)acetic acid	[*93-76-5*]	$C_8H_5Cl_3O_3$	225.49
Fenoprop	2-(2,4,5-trichlorophenoxy)propionic acid	[*93-72-1*]	$C_9H_7Cl_3O_3$	269.53

∗ Melting point data in Table 2.
∗∗ The trivial names MCPA, MCPB, and mecoprop are derived from former chemical nomenclature using 2-methyl-4-chlorophenoxy as the basic unit.

pared by chlorination of phenol and contains 2,6-dichlorophenol and 2,4,6-trichlorophenol as major impurities. These byproducts are not formed if the chlorination is carried out in liquid sulfur dioxide below its boiling point [10].

Similarly, the chlorophenol used to manufacture MCPA, MCPB, and mecoprop is obtained by chlorination of *o*-cresol, a starting material in abundant supply in Europe particularly in Britain, as a product of coal tar distillation. Although chlorination occurs mostly at the 4-position, large amounts of 6-chloro- and 4,6-dichloro-2-methylphenol are also produced when chlorine or alkali hypochlorites are used. A much purer product is obtained when sulfuryl chloride is used for chlorination [10].

A completely different route is used for production of 2,4,5-trichlorophenol by *hydrolysis of 1,2,4,5-tetrachlorobenzene*:

where R^1 is H or CH_3. $R^2R^3R^4N$ is an alkylamine, R^5OH is an alcohol, and MOH is an alkali metal base. One chlorine substituent is replaced by using alcoholic alkali under pressure, with careful control of temperature to avoid formation of highly toxic 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) by exothermic condensation of two molecules of 2,4,5-trichlorophenol. Trace amounts of TCDD are carried over into 2,4,5-T and, to a lesser extent, into fenoprop (also known as silvex or 2,4,5-TP). The impurities in technical-grade 2,4,5-T may vary among producers and among batches of the same product [9, p. 38].

Chlorination of phenoxyacetic acid is another important synthetic route for production of 2,4-D. However, the product may contain a high level of 2,4-dichlorophenol, which has a very strong odor [5]. Chlorination of tolyloxyacetic acid produces mainly the 4-chloro derivative, with small amounts of 6-chloro and other impurities [10].

Phenoxybutyric acid derivatives, such as 2,4-DB and MCPB, are generally prepared by using *γ-butyrolactone* to acylate the chlorophenols [5].

An alternate route to phenoxy acids is by formation of the appropriate *chlorophenolate* and reaction with an ester of the appropriate chloroalkanoic acid [10]. The resulting phenoxy ester can be saponified and acidified to release the free acid, or the phenoxy ester can be used directly for preparation of oil-soluble herbicide formulations. However, these reaction conditions could lead to condensation of chlorophenols to dioxins, and may have been responsible for the di-, tri-, and tetrachlorodibenzo-*p*-dioxins found in certain 2,4-D products in Canada [20]. The 2,3,7,8-tetrachloro isomer has not been detected in products other than 2,4,5-T and fenoprop.

a) Neutralization vessel; b) Reaction kettle; c) Acidification kettle; d) Precipitation vessel; e) Suction filter; f) Drier; g) Mill; h) Filter; i) Esterification kettle; j) Amination kettle

Platinum-catalyzed oxidation of 2-phenoxyethanols has also been used to synthesize phenoxyacetic acids [21]. However, this method may not be commercially feasible because of cost.

Volatile products containing isopropyl or butyl esters of 2,4-D and 2,4,5-T were produced in large quantities prior to 1970, particularly for use as defoliants in the Vietnam conflict. However, most countries now permit use of only *low-volatile products* containing salts or derivatives with a long side-chain, such as isooctyl, butoxyethyl, or PGBE (polypropylene glycol butyl ether) esters of chlorophenoxyalkanoic acids [7], [9], [10].

*Water-soluble salts*of phenoxy acids are formed with alkali metal cations, ammonia, and organic amines, such as dimethylamine, triethylamine, or triisopropanolamine. Magnesium and calcium salts of 2,4-D and MCPA are considerably less soluble in water than are sodium and potassium salts [10]. Oil-soluble salts are prepared from long-chain amines derived from fatty acids [1], [10].

Process *waste streams* are treated by a combination of methods to reduce levels of chlorophenolic and chlorophenoxy compounds to low ppm values prior to discharge to public waters. Methods include steam stripping, solvent extraction, carbon adsorption, resin adsorption, chlorine oxidation, biological oxidation, and incineration.

Principal *manufacturers* of technical-grade acids and derivatives are Akzo Zout in the Netherlands, BASF and Bayer in the Federal Republic of Germany, Chemie-Linz in Austria, Dow in the United States and Brazil, Koge in Denmark, A. H. Marks and May & Baker in the United Kingdom, Rhône-Poulenc in France, and Vertac in the United States. About 25 % of the world capacity in 1982 was located in East Europe, mainly in Czechoslovakia, German Democratic Republic, Hungary, Poland, Romania, and USSR. Phenoxy herbicides are also produced in Argentina, Australia, India, Japan, Mexico, New Zealand, the People's Republic of China, the Philippines, and Taiwan. Several major manufacturers have discontinued production or sold their facilities since 1982.

End-use products are formulated by most manufacturers of technical chlorophenoxyalkanoic acids and derivatives, as well as by many additional distributors worldwide. Numerous trade names have been listed for phenoxy herbicide products [1–4], [7], [10], [18], but many such names were discontinued or were transferred to other companies.

3. Quality Specifications

International specifications for phenoxy herbicides and other pesticides have been developed by the United Nations Food and Agriculture Organization (FAO). Methods of analysis have been tested and approved by the Collaborative International Pesticides Analytical Council

(CIPAC) and the Association of Official Analytical Chemists (AOAC).

Updated specifications for phenoxyalkanoic herbicides were consolidated in a booklet issued by FAO in 1984 [22]. The values for technical acids summarized in Table 2 have "full" status for MCPA and 2,4,5-T and "provisional" status for the others. Other parameters for identification include IR spectra, GLC retention times, and R_f values for TLC analyses. The FAO also lists specifications for salts and esters, aqueous salt solutions, emulsifiable ester concentrates, and mixtures containing phenoxy salts or esters, all given in terms of the acids released by hydrolysis of these derivatives. Complete names are required of the base components of salts and the alcohol components of esters in phenoxy herbicide products.

The U.S. Environmental Protection Agency (EPA) has issued regulations and guidelines for registration of pesticide products [23]. These include chemistry requirements for the identification of all impurities and byproducts down to 0.1 % in technical-grade products.

For many years, the *analytical methods* used for assessing the quality of phenoxy herbicides involved simple acid–base titration, or determination of total chlorine released by pyrolysis of technical-grade acids and derivatives [2–4], [18]. These nonspecific, and therefore inaccurate methods have been superseded by GLC procedures [1], [24], [25], and, by isomer-specific high-pressure liquid chromatography [26–28]. Similar methods for other phenoxy herbicides are undergoing collaborative testing and will likely be required in the future [10].

4. Uses

Distribution, marketing, and use of pesticides are closely regulated in most countries, either through national statutes or by indirect reliance on reviews by expert committees under the auspices of international agencies, such as FAO, the World Health Organization (WHO), and the Codex Food Standards Programme of the United Nations.

Labels on containers of phenoxy herbicides are registered individually in most exporting and importing countries (and even in states within countries). These labels specify the nature and content of active ingredients; give precautions to be taken to avoid hazard to humans, livestock, wildlife, or the environment; and describe precise conditions for each approved use.

Phenoxy herbicides are used primarily for *selective control of broadleaf weeds* in cereal grains, pastures, and turf; and for removing unwanted brushy species in rangeland, forests, and noncropland. Rates of application range from as low as 0.25 kg/ha in grain crops to as high as 16 kg/ha for spot treatment of individual trees in rights-of-way. Very dilute solutions of 2,4-D and fenoprop derivatives have also been used as plant growth regulators in fruit orchards.

The choice of products depends on the species of plants to be controlled [1–4], [6]. For example, 2,4,5-T and fenoprop are effective on woody plants and herbaceous weeds that are resistant to 2,4-D. Dichlorprop, fenoprop, and mecoprop are effective for controlling chickweed and other unwanted plants in lawns and turf. The butyric acid derivatives 2,4-DB and MCPB can be used on sensitive crops, such as peas, peanuts, soybeans, and seedling forage legumes (alfalfa and clover), because they are inactive as herbicides until converted to the acetic acid derivatives by β-oxidation of the side-chain [6].

Phenoxy herbicides are applied alone or as mixtures with other herbicides in solutions, dispersions, or emulsions in water or oil; equipment that produces large droplets is used to avoid spray drift. Although volatile derivatives, such as isopropyl and butyl esters of 2,4-D and 2,4,5-T, are effective for controlling weeds and brush in noncropland, treatments with low-volatile long-chain esters and amine salts are less likely to cause damage to susceptible off-target crops or desirable vegetation. Granular salt formulations of 2,4-D or fenoprop have been used for aquatic weed control, but longer-acting ester formulations are more effective.

Formulated phenoxy herbicide products generally contain inert ingredients to prevent precipitation of salts when these formulations are diluted with hard water, or to help disperse or emulsify esters in oil or oil/water mixtures. Oil concentrates are less corrosive than emulsifiable concentrates or salt solutions, but are more flammable and require more restrictive labeling for safe transport, storage, and handling.

Table 2. International FAO specifications for technical chlorophenoxyalkanoic acids [22]

Common name	*mp*, °C	Acid (anhydrous) [a], g/kg min.	Free phenol [b], g/kg max.
2,4-D	137 – 141	890 ± 25	5
2,4-DB	114 – 119	890 ± 30	20
Dichlorprop	113 – 118	890 ± 25	15
MCPA	118 – 119 [c]	840 ± 20	10
MCPB	100 [c]	840 ± 30	30
Mecoprop	94 – 95 [c]	840 ± 40	15
2,4,5-T [d]	150 – 156	910 ± 30	5
Fenoprop [d]	175 – 181	890 ± 40	15

[a] The water content of dry acids should not exceed 15 g/kg; the approximate water content should be stated for wet acids containing more than 15 g/kg.
[b] The free phenol content is expressed as the parent phenol in terms of the anhydrous phenoxy acid content.
[c] As listed in [1], [2]; may be 99 – 107 °C for technical-grade MCPA.
[d] Maximum content of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) is 1×10^{-8} expressed as 0.01 mg/kg of the 2,4,5-T or fenoprop content on an anhydrous basis.

Only inert ingredients approved by the EPA are permitted in products to be used on food crops in the United States [23].

5. Toxicology and Occupational Health

Numerous toxicological studies have been conducted with phenoxy herbicides in laboratory animals, livestock, birds, and fish. In addition, pharmacokinetic studies in animals and in humans have demonstrated that these compounds do not accumulate in the body. Detailed summaries of findings are provided in several extensive reviews [7], [9], [11–18], [29–31].

Chlorophenoxyalkanoic acids, derivatives, and formulated products are *classified as moderately toxic,* based on acute studies using single large doses administered by oral, dermal, or inhalation routes in various species of animals [1–4]. According to World Health Organization (WHO) guidelines, 2,4-D and 2,4,5-T are in class II (moderately hazardous) with acute oral LD_{50} values of 375 and 500 mg/kg of body weight in rats [32]. Other phenoxy herbicides are in class III (slightly hazardous), with acute oral LD_{50} values in mg/kg for rats as follows: fenoprop (650), MCPB (680), 2,4-DB (700), MCPA (700), dichlorprop (800), and mecoprop (930). Acute oral toxicity values for salts and esters are comparable to those for the acids, on an acid equivalent basis [7], [9].

Dogs appear to be more sensitive to chlorophenoxyalkanoic acids than rats, whereas birds are less sensitive [7] and livestock can tolerate higher doses without apparent effect [9]. Phenoxy herbicides are not toxic to bees. The LC_{50} in fish may range from less than 1 mg/L for esters to greater than 100 mg/L for acids and salts [7].

Dry acids are only slightly irritating to eyes and skin, but concentrated solutions or wetted powders may cause burns if contact is prolonged or repeated [31]. In rabbits, no significant adverse systemic effects resulted from exposure for 3 weeks to dilute solutions of formulated products containing dimethylamine salt, isooctyl ester, or butyl ester of 2,4-D [31].

Although phenoxy compounds are not acutely toxic in dermal and inhalation studies, potential occupational exposure is greater by these routes than by ingestion. Adequate precautions should be taken to avoid contamination of skin with technical-grade materials or concentrates, and to avoid prolonged breathing of the vapors or dusts. Occupational exposure limits have been set at 10 mg/m^3 for 2,4-D and 2,4,5-T in both the United States (TWA) and the Federal Republic of Germany (MAK).

Effects of 2,4-D in humans were reviewed in 1984 by an international committee convened by WHO [17]. Signs and symptoms of acute overexposure occurred only after ingestion of large amounts of 2,4-D products in suicide cases, or where poor occupational hygiene led to pronounced dermal exposure. The acute no-observed – adverse-effect level for biological effects was estimated to be as high as 36 mg/kg of body weight in humans for 2,4-D or its equiv-

alent in alkali salts, amine salts, or esters. On the basis of available studies on amounts of 2,4-D or 2,4,5-T absorbed through occupational exposure, the margin of safety is at least 360-fold for spraying crews and much greater than 1000-fold for the general population in areas where 2,4-D is used [17].

Little or no effects were seen in livestock or laboratory animals other than dogs given repeated oral doses up to 50 mg/kg of 2,4-D, 2,4,5-T, MCPA, or fenoprop, as acids, salts, or esters [7], [9]. Reversible embryotoxic or fetotoxic effects were seen in offspring of pregnant rats and mice given daily doses above 40 mg/kg during organogenesis [7], [9], [11–18]. However, true teratogenic effects, such as cleft palate, were seen only in mice given 2,4,5-T, possibly due to high levels of TCDD contaminant in some samples of technical-grade acid and esters [9, p. 115].

Dietary feeding studies have also been conducted with phenoxy acids and derivatives in rats, dogs, and mice for periods ranging from 3 months to 2.5 years to evaluate potential for causing chronic toxicity, cancer, or reproductive effects. Details are provided in extensive reviews by National Research Council of Canada [7], WHO [11–18], and others [30–37]. The major findings are as follows:

In chronic feeding studies with *2,4-D* conducted by U.S. Food and Drug Administration [33], dogs and rats were fed for 2 years on diets containing up to 500 and 1250 ppm technical-grade acid, respectively, and pregnant rats were fed up to 1500 ppm in the diet during three generations of reproduction with two litters per generation. No significant effects were seen in any of the dogs, nor in rats fed up to 625 ppm in the diet equivalent to a dosage level of 31 mg kg^{-1} d^{-1} in this species. There was no effect on fertility nor on average litter size at any dose, but at 1500 ppm the percentage of young born that survived to 21 days was sharply reduced and the weaning weight was depressed. On the basis of these studies, the acceptable daily intake (ADI) for 2,4-D in humans was estimated by the 1971 WHO Expert Committee on Pesticide Residues at 0.3 mg kg^{-1} d^{-1} with a 100-fold safety factor over the no-effect level in rats [12]. Additional studies are under way in the United States to fulfill EPA requirements for registration of pesticides used in food crops [23].

Four long-term feeding studies have been conducted with *2,4,5-T,* each study at dosage levels of 3, 10, and 30 mg kg^{-1} d^{-1} in rats. Effects were seen at the high dose, and to a lesser extent at the middle dose, in studies conducted by Dow in the United States using purified 2,4,5-T ($<5\times10^{-10}$ TCDD) in the diet of rats for 2 years [34] or during three generations of reproduction [35]. On the other hand, all dose groups were comparable to controls in studies conducted in the Federal Republic of Germany using technical-grade 2,4,5-T (5×10^{-8} TCDD) in the diet of rats from before conception through weaning to age 130 weeks or through three generations of reproduction [14]. On the basis of these studies, the 1981 WHO Expert Committee estimated the ADI in humans at 0.03 mg kg^{-1} d^{-1} for 2,4,5-T containing no more than 1×10^{-8} TCDD [16].

Unpublished studies with *fenoprop* have been summarized in two reviews [30], [31]. The dosage levels causing no significant toxicological effect were 7 mg kg^{-1} d^{-1} in 90-day feeding studies with the sodium salt and PGBE esters in rats and the potassium salt in dogs, and essentially 2.6 mg kg^{-1} d^{-1} in 2-year feeding studies with the potassium salt in both rats and dogs.

Subchronic feeding studies with *MCPA* and *mecoprop* have also been reviewed [7], [9]. When diethanolamine salts of these compounds were fed to rats at up to 2500 ppm in the diet for 7 months, the only effect noted was unspecified mortality, mainly due to infection at the maximum dose [36]. On the other hand, no mortalities were reported when MCPA as the sodium salt or mecoprop as the acid was fed at levels up to 3200 ppm in the diet of rats for 3 months. The only effects noted were reduced food consumption and decreased weight gain at the highest dose [37]. Additional studies with MCPA are under way to meet current requirements in the United States for reregistration of pesticides used in food crops [23].

The *potential human carcinogenicity* of chlorophenoxyalkanoic acids and their derivatives has been evaluated by several expert groups. Committees convened by the International Agency for Research on Cancer (IARC) reviewed all of the above studies in rats, numerous studies in mice conducted by U.S. National Cancer Institute, and several epidemiological studies in humans occupationally exposed to

formulated products [18]. Both *2,4-D* and *2,4,5-T* and their esters were assigned to group 3 (evidence inadequate for carcinogenicity to humans and animals, and for activity in short-term tests) [18, 1982, pp. 101 – 103, 235 – 238]. For *MCPA*, no adequate data were available to evaluate carcinogenicity to experimental animals or humans [18, 1983, pp. 255 – 269]. On the other hand, *TCDD* was classified in group 2B (sufficient evidence for carcinogenicity to animals and inadequate evidence in humans and in short-term tests [18, 1982, pp. 238 – 243], whereas *chlorophenols* and *phenoxyacetic acid herbicides* (occupational exposure) were generically classified in group 2B on the basis of only limited evidence for carcinogenicity to humans [18, 1982, pp. 88 – 89, 211 –212].

6. Biochemical and Environmental Aspects

The following observations summarize findings reported in extensive reviews on biochemistry, metabolism, degradation, and residues of phenoxy herbicides [6], [7], [9], [11–18], [31], [38], [39].

The *solubility* of chlorophenoxyalkanoic acids ranges from 45 to 1300 mg/L in water and from 0.1 to 153 g/100 mL in CCl_4 and ethanol, respectively [6]. These compounds are relatively strong acids, with p*K* values ranging from 2.64 for 2,4-D to 6.21 for MCPB [6], and exist mainly as organic anions at the pH of living tissues. Salts dissociate in aqueous media, and esters are rapidly hydrolyzed to acids by enzymatic action in animals, plants, and soil [6].

Phenoxy acids and derivatives are rapidly *absorbed* from the gastrointestinal tract in animals and are excreted in urine, largely as free acids, with a half-life of less than 1 day [38]. Doses greater than 50 mg/kg of body weight may saturate the excretory mechanism, particularly in dogs and pigs [9]. Fenoprop is excreted more slowly than 2,4-D and 2,4,5-T, and appears partly in conjugated form in urine. In humans, small oral doses of 2,4-D or 2,4,5-T (5 mg/kg) or fenoprop (1 mg/kg) were handled much as in rats, indicating little likelihood for accumulation from repeated exposure [31]. Absorption into the body is slower from dermal exposure than from oral ingestion [17], [39].

The phenoxy ether link is stable in plants and animals, but is cleaved by bacterial action in soil and in the rumen of cattle and sheep [38]. The rate of cleavage is inhibited by substitution of a third chlorine at the meta position on the ring and is sterically hindered by the angular methyl group in the 2-propionic acid side-chain. Thus, 2,4,5-T and fenoprop accumulate in the liver and kidney of cattle and sheep ingesting high levels in the diet [38].

The first step in *degradation* of chlorophenoxy acids and chlorophenols occurs by hydroxylation at the 4-position with shift of the 4-chloro group to the 3- or 5-position (NIH shift). This reaction also is inhibited by the presence of a *m*-chloro substituent; thus, residues of 2,4,5-trichlorophenol appeared in the milk of cows and in the liver and kidney of cattle maintained on feed containing 100 or 300 ppm 2,4,5-T, respectively [38].

The rate of *microbial degradation* of chlorophenoxyalkanoic acids in the environment depends on a number of factors, including sunlight, temperature, moisture and organic matter in soil, and whether the organisms were adapted by repeated treatment [6], [7], [9]. Under field conditions favorable for degradation, 2,4-D disappears within about 2 – 3 weeks, whereas other phenoxy herbicides disappear more slowly [6]. The average half-lifes in a laboratory study were 4, 10, 17, and 20 days for 2,4-D, dichlorprop, fenoprop, and 2,4,5-T, respectively, when added as dimethylamine salts at about 5 ppm in three soils containing partially decomposed litter obtained from two forest sites and one grassland site in Oklahoma [40].

Photodegradation is rapid when phenoxy herbicides are exposed to sunlight in water containing dissolved organic matter, and the resultant chlorophenols are photolyzed even more rapidly than the parent acids [7], [9]. The dioxin impurity TCDD is also degraded rapidly by sunlight, particularly in the presence of its herbicide carrier on the surface of leaves or in the presence of other hydrogen donors dissolved in water [7].

Plants treated with phenoxy herbicides rapidly hydrolyze esters and salts to the parent acids, which form ether-soluble *conjugates* with amino acids or water-soluble conjugates with sugars, depending on the relative susceptibility or resistance of the plants to the herbicides [6]. *Analyses for residues* in treated crops

and environmental samples involve extraction with organic solvents under acid conditions [10] or with polar solvents under alkaline conditions [41]. Quantification is best accomplished by conversion to volatile esters and measurement by electron capture gas chromatography (EC/GC). Other methods include colorimetry and thin-layer chromatography [4], [10].

Tolerances have been established in the United States for residues of 2,4-D and MCPA in a number of food and feed crops, and in milk and meat [42]. Permitted levels range from 0.05 ppm (the detection limit) in strawberries, poultry, and eggs to 1000 ppm on grass immediately after treatment with 2,4-D at high rates. Similarly, international maximum residue limits (MRLs) have been recommended for 2,4-D and 2,4,5-T by FAO [11–13], [15], and have been accepted by many member countries attending annual meetings of the United Nations Codex Committee on Pesticide Residues [43]. However, residues of chlorophenoxyalkanoic acids have seldom been detected in monitoring studies conducted on domestic and imported foods in a number of countries [44].

Guidelines for *drinking water* quality issued in 1982 by WHO recommend a maximum concentration level of 100 µg/L for 2,4-D in water [45].

1. Introduction

Chlorosulfuric acid [*7790-94-5*], M_r 116.53, is also referred to in the literature as chlorosulfonic acid, sulfuryl hydroxychloride, sulfuric chlorohydrin, sulfonic acid monochloride, and chlorohydrated sulfuric acid.

Chlorosulfuric acid is a colorless, mobile, extremely reactive liquid. It fumes very strongly in air and, consequently, has been used as a military smoke-generating agent, being mixed with oleum for this purpose (ca. 50 – 65 wt % HSO_3Cl, 50 – 35 wt % SO_3). A very thick, opaque mist is produced when 2 L of chlorosulfuric acid is mixed with 1000 m^3 of air.

Chlorosulfuric acid is highly corrosive and hygroscopic. It decomposes explosively in the presence of water, forming sulfuric acid and hydrogen chloride. A. WILLIAMSON first prepared chlorosulfuric acid in 1854 [5].

2. Physical Properties

The values of physical constants quoted in the literature should not be accepted uncritically. Chlorosulfuric acid is difficult to purify and has frequently been used in an impure state for experimental determinations. Table 1 shows the best values available. Very pure chlorosulfuric acid can be obtained by fractional crystallization [6].

Table 1. Physical properties of chlorosulfuric acid

Property	Value
Freezing point *fp*	− 80 to − 81 °C
Boiling point *bp* (decomp.)	151 – 152 °C
Vapor pressure	
(p in mbar at T in K)	$\log p = 9.495 - 2752/T$
(p in Pa at T in K)	$\log p = 11.495 - 2752/T$
Density∗	$d_4^{20} = 1.753$
	$d_4^{-70} = 1.90$
	$d_4^{-10} = 1.80$
	$d_4{}^t$ (0 – 100 °C)
	$= 1.7847 - 1.616\,t \times 10^{-3}$
	$+ 1.21\,t^2 \times 10^{-6}$
	$- 4.1\,t^3 \times 10^{-9}$
Specific heat capacity (15 – 80 °C)	1.18 kJ kg^{-1} K^{-1}
Heat of vaporization (at boiling point)	53.6 kJ/mol (460 J/g)
Heat of solution in water (at 18 °C)	168.7 kJ/mol
Heat of formation from elements (at 25 °C)	− 597.5 kJ/mol
Viscosity at − 31.6 °C	10 mPa s
at − 17.8 °C	6.4 mPa s
at 15.6 °C	3.0 mPa s
at 49 °C	1.7 mPa s
Refractive index n_D^{14}	1.437
Dielectric constant (at 15 °C)	60 ± 10
Electrical conductivity (at 25 °C)	$0.2 - 0.3 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$
Specific magnetic susceptibility	− 0.402

∗ Because chlorosulfuric acid decomposes at the boiling point, its vapor density cannot be determined precisely.

The large heat of vaporization is explained by the strong association of chlorosulfuric acid molecules, which results from hydrogen bonding [7]. Chlorosulfuric acid is soluble in methylene chloride, chloroform, 1,1,2,2-tetrachloroethane, 1,2-dichloroethane, acetic acid, acetic anhydride, trifluoroacetic acid, trifluoroacetic anhydride, sulfuryl chloride, liquid

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a07_017

sulfur dioxide, and sparingly soluble in carbon tetrachloride and carbon disulfide. It reacts with alcohols, ketones, ethers, and dimethyl sulfoxide.

Whereas sulfur trioxide is miscible in all proportions with chlorosulfuric acid, the limit of solubility of free hydrogen chloride is 0.5 wt % at 20 °C and atmospheric pressure [8].

Warning: Care must be taken when working with chlorosulfuric acid in the presence of solvents; an increase in temperature can lead to violent reactions, particularly when catalysts are also present.

3. Chemical Properties

Chlorosulfuric acid is a strong acid, stable under normal conditions. The tetrahedral molecule [9] contains a relatively weak S – Cl bond [10]. Its force constant is only about one-third that of the single bond in S – O(H) [11]. Depending on the co-reactant, the solvent (if any), the temperature, and the amount of excess HSO_3Cl present, the first step of the reaction will be the formation of free chlorine atoms [12], chlorine ions, or protons [10], [13]. Prolonged heating or distillation, especially in vacuo, leads to partial decomposition to hydrogen chloride, chlorine, sulfur dioxide, sulfuryl chloride, pyrosulfuryl chloride, and sulfuric acid [6].

If chlorosulfuric acid is stored in the presence of an excess of sulfur trioxide, the following reaction occurs [6]:

$$2\,HSO_3Cl + SO_3 \longrightarrow H_2SO_4 + S_2O_5Cl_2$$

In freshly prepared and cooled solutions chloropyrosulfuric acids are formed by the following equilibrium reaction:

$$H(SO_3)_nCl + SO_3 \rightleftharpoons H(SO_3)_{n+1}Cl$$

where $n = 1$, 2, or 3 [14]. Chloropyrosulfates are obtained from the reaction of alkali metal chlorides with sulfur trioxide in liquid sulfur dioxide at − 12 °C [15].

Many reactions with chlorosulfuric acid can be carried out at low temperatures, which is facilitated by its low melting point. Sulfonic acids are produced with equimolar quantities of aromatic hydrocarbons under mild conditions; the reaction usually does not affect other substituents present in the molecule. However, in some cases, amino groups must be protected by acylation from reacting with chlorosulfuric acid. Side reactions lead to the formation of small quantities of sulfonyl chlorides, which usually react further with aromatic hydrocarbons to form sulfones (→ Benzenesulfonic Acids and Their Derivatives). The sulfonyl chlorides are used as intermediates in the manufacture of pharmaceuticals or dyes.

Depending on the reaction conditions, sulfonyl chlorides, sulfones, or chlorinated aromatic hydrocarbons can be obtained by using an excess of chlorosulfuric acid [16], [17]. Sulfonyl chloride formation takes place in two steps: formation of a sulfonic acid followed by an equilibrium reaction [10], [18], [19]:

$$ArH + ClSO_3H \rightleftharpoons ArSO_3H + HCl$$

$$ArSO_3H + ClSO_3H \rightleftharpoons ArSO_2Cl + H_2SO_4$$

This equilibrium can be shifted to the right by reacting the sulfuric acid formed with pyrosulfuryl chloride or with thionyl chloride. The reaction with pyrosulfuryl chloride leads to the formation of chlorosulfuric acid and sulfur trioxide; thionyl chloride reacts with the nascent sulfuric acid to form chlorosulfuric acid, hydrogen chloride, and sulfur dioxide [20].

The reaction of chlorosulfuric acid with aliphatic hydrocarbons is slow, provided there are no double bonds or other reactive groups present. Therefore, long-chain saturated fatty alcohols react with chlorosulfuric acid to form the corresponding sulfates without chain cleavage or discoloration of the product. This type of reaction is used on a large scale in the manufacture of detergents:

$$ROH + HSO_3Cl \longrightarrow HCl + ROSO_3H$$

Both chlorosulfuric acid and fluorosulfuric acid have been proposed as polymerization catalysts [21]. Many of the reactions of chlorosulfuric acid have been reviewed by Jackson [22]. Special information on this subject can be found in refs. [23–31].

4. Production

All the industrial routes to chlorosulfuric acid are based on the reaction of hydrogen chloride with sulfur trioxide:

$$HCl + SO_3 \longrightarrow HSO_3Cl$$

Earlier processes made use of contact process gas which contains 6 – 7 % SO_3 [32], but today it is more usual to use pure sulfur trioxide. Waste-gas problems are thereby dealt with more easily, and a more compact plant design is possible. Production processes vary both in the manner of bringing the two raw materials into contact and in the methods of removing the heat of reaction.

The reactor can be a packed column with a chlorosulfuric acid spray at the top and hydrogen chloride and sulfur trioxide entering at the bottom [33]. In this case, the reaction and the heat removal both take place in one piece of equipment. Alternatively, it is possible to separate these steps by first mixing the components intensively in a separate mixer such as a mixing nozzle [34]; the hot reaction product is then quickly cooled with cold chlorosulfuric acid in a packed column or other suitable unit. Cooling has also been suggested by means of a water-cooled condenser [35]. In one modification of the process, the first product is chlorosulfuric acid which contains a small excess of sulfur trioxide; this is then cooled and saturated with hydrogen chloride in a bubble column [36]. The off-gas is normally scrubbed, first with 98 % sulfuric acid and then with water.

Several patents describe the recycling of recovered hydrogen chloride and sulfur trioxide [37]. The heat of formation of chlorosulfuric acid can be used to evaporate sulfur trioxide from low-percentage oleum. The sulfur trioxide then reacts with hydrogen chloride at subatmospheric pressure [38].

Construction Materials. Because commercial chlorosulfuric acid should contain very little or no iron, suitable construction materials for reactors, containers, etc., are enamel, glass, aluminum, or steel lined with polytetrafluoroethylene (PTFE) [39].

Analysis and Quality Requirements. The usual method for analyzing chlorosulfuric acid involves hydrolysis of the acid to form SO_3 and HCl, followed by determination of the total acidity and chloride content. When the content of HSO_3Cl, H_2SO_4, and free SO_3 or HCl is calculated, the amount of water that is absorbed by SO_3 to form H_2SO_4 must be taken into account. Variations of this method are described in ref. [31]. The presence of sulfuryl and pyrosulfuryl chloride (SO_2Cl_2 and $S_2O_5Cl_2$) must be determined by special methods [32]. Specific color reactions in combination with too low a melting point identify chlorosulfuric acid producing a cherry red color with tellurium powder or a moss green color with selenium [6].

A product low in iron is normally required, with the following analysis:

HSO_3Cl	98 – 99.5 %
H_2SO_4	0.2 – 2 %
Free SO_3	0 – 2 %
Free HCl	0 – 0.5 %
Fe	5 – 30 ppm

5. Safety Precautions, Transportation

Because chlorosulfuric acid is very aggressive, the regulations dealing with hazardous materials apply [40]. Chlorosulfuric acid reacts violently with water and, with moist air, decomposes to form hydrogen chloride and sulfuric acid mist. All vessels, pipes, metallic hoses, etc., should be dry. Even small leakages must be prevented. Containers should be handled with care: they must never be dropped because a slight internal pressure may build up. The stopper should be opened only with a wrench and not with hammer and chisel. Containers must be emptied by siphoning and not by the use of compressed air. The access of moist air can be avoided by tight connection to a gas bypass. After each removal of chlorosulfuric acid the container must be tightly closed.

Although chlorosulfuric acid itself is not combustible, it can induce ignition of combustible materials. Reaction with moist metals can produce hydrogen. Naked flames must therefore be avoided in the neighborhood of containers or pipes. If welding must take place, the safety precautions pertaining to hydrogen should be observed. Enclosed spaces in which

chlorosulfuric acid is being handled must always be well ventilated. Acid-proof clothing, goggles, and gloves must be worn. A full face gas mask with a filter element for absorbing acid fumes, and safety boots must be at hand. Polychloroprene coated with a copolymer of vinylidene fluoride and hexafluoropropylene would be a suitable material for gloves, protective clothing, and full-face gas masks. Boots could be made of poly (vinyl chloride). Contaminated clothing must be changed without delay.

Small spillages of chlorosulfuric acid must be washed away with water, and all necessary safety measures should be observed; the spilled material should be downwind and the area cordoned off. A high-velocity jet of water should not be used; the spillage should rather be worked from the outside toward the middle, preferably by means of a hose with a spray nozzle attachment. The area can then be neutralized with sodium carbonate, sodium hydrogen carbonate, or lime.

Chlorosulfuric acid must not be allowed to leak into the sewerage system or the soil. Spilled acid may be blanketed with paraffin oil or FEP film (perfluorinated ethylene – propylene copolymer). The contaminated area will reveal itself by fog formation; and this can be prevented from spreading by shielding with water. Personnel involved in such cleaning operations must wear full protective clothing and use compressed air breathing apparatus.

Transportation. Differing regulations apply to transportation by road, rail, or sea [41]. Road transportation may utilize barrels made from aluminum or iron.

Chlorosulfuric acid should, however, be carried by rail whenever possible. The construction material for tanks of rail or road trucks is usually stainless steel, but enameled steel may also be used.

6. Uses and Economic Aspects [42]

The breakdown of chlorosulfuric acid production according to end use is as follows:

Detergents	40 %
Pharmaceuticals	20 %
Dyes	15 %
Crop protection	10 %
Ion-exchange resins[43], plasticizers, and others	15 %

The following companies are published as manufacturers of chlorosulfuric acid:

Europe [42]:	BASF, Ludwigshafen	D
	Bayer, Leverkusen	D
	UCB, Ostende	B
	EniChem, Pieve-Vergonte	I
	Säurefabrik, Schweizerhalle	CH
	ICI, Runcorn	GB
	Tiszamenti, Szolnok	H
USA [43]:	DuPont, Wurtland, Kent.	US
	Gabrieil Chem., Geismar, Lous.	US
Asia [44]:	Mitsubishi, Kitakyushu	J
	Nippon Soda, Toaoka	J
	Nissan Chem., Neigun	J
	Takuyama, Tokuyama	J
	Choheung, Seoul	KOR
	Chen Yeh, Taipei	Taiwan
	Chung Hwa, Yingko	Taiwan
	Kuo Kai, Taipei	Taiwan

With regard to the annual production of chlorosulfuric acid in recent years, no reliable figures are available in the relevant literature.

7. Toxicology and Occupational Hygiene [45]

Chlorosulfuric acid is a strong acid and dehydrating agent that produces severe burn of the skin. The acid fog formed in moist air strongly irritates the respiratory tract and eyes. Contact with the skin or inhalation of the vapor must be avoided under any circumstances.

If there is accidental contact with the skin or eyes, the affected part must be washed immediately with large amounts of water; medical help should then be sought as soon as possible.

No MAK or TLV has been established for HSO_3Cl but the values for its principal decomposition products are:

H_2SO_4: MAK and TLV 1 mg/m^3 (1995)
HCl: MAK and TLV 7 mg/m^3 (1995)

To be called chocolate a product must partially consist of ingredients derived from cocoa beans and strict regulations exist as to how the different chocolate types can be described on their packaging. This article looks at the history of drinking and solid eating chocolate, before describing the growing and processing of the cocoa beans themselves. The chocolate making procedure is then reviewed, followed by some of the methods used to process the liquid chocolate. As the main fat, cocoa butter, can solidify in six different forms, the crystallisation principles are particularly important. Finally the most important countries are compared with respect to their cocoa growing tonnage, chocolate manufacturing output and consumption per head of population.

1. Definitions

Cocoa beans are the fermented and dried seeds of cocoa trees. *Cocoa nibs* (the cotyledons from the beans) are the product obtained from cleaned raw or roasted cocoa beans by breaking them and removing the cocoa bean shell. The residual amount of shell and germ should not exceed 5 % (calculated on fat-free dry cocoa mass) although this is no longer a legal requirement within the EC.

Cocoa mass, also known as *cocoa liquor*, is the product obtained by grinding raw or roasted non-alkalized or alkalized cocoa nibs from which no cocoa butter has been removed.

Cocoa powder is made by partly defatting the cocoa mass by pressing it and then pulverizing the remaining cocoa press cake. Cocoa nibs for producing cocoa mass may be treated (alkalized) with alkali carbonate or other materials which are nutritionally and physiologically harmless, such as ammonium salts, magnesium oxide, or calcium oxide. This makes the powder less likely to sediment out when it is used as a drink. The alkalinity of the cocoa ash must not exceed the equivalent of 160 mL of 1 N alkali hydroxide solution per 100 g fat-free cocoa solids. Ordinary *cocoa powder* must contain a minimum of 20 % cocoa butter calculated on dry solids [1]. *Fat reduced cocoa powder* in the EC describes any powder with less than 20 % cocoa butter. *Sweetened cocoa powder* is a mixture of cocoa powder and sucrose. The proportion of cocoa powder must be a minimum of 25 %, which is the same as for *drinking chocolate*.

Although no longer described in the regulations several types of cocoa butter are found commercially. *Pressed cocoa butter* must have been obtained exclusively by mechanical extraction (pressing) from broken nibs or cocoa mass. The nibs or cocoa mass may have been treated with alkali prior to pressing.

Expeller cocoa butter may be made by pressing the whole beans including the shell, whereas *refined cocoa butter* can be obtained by solvent extracting the residues from the cocoa press.
Chocolate must contain cocoa mass — for the dark or milk varieties — or cocoa butter, for white chocolate. The proportions of the other ingredients that can be used for a product which can be described as chocolate, varies from country to country. Most, however, follow one of three sets of regulations, i.e., European [2], USA and Codex Alimentarius [3]:

1) *Dark chocolates* are mixtures of cocoa mass or cocoa powder, cocoa butter and sucrose. The proportion of cocoa constituents (fat-free dry cocoa solids and cocoa butter) must be a minimum of 35 % and the proportion of fat-free dry cocoa mass must not be less than 14 % with a minimum of 18 % of cocoa butter. Some dark chocolates contain milk fat in order to extend the shelf-life by maintaining the gloss for a longer period.
2) *Milk chocolates* are mixtures of cocoa mass or cocoa powder with cocoa butter, sucrose, and dried milk solids. The proportion of cocoa constituents (fat-free dry cocoa solids and cocoa butter) must be a minimum of 25 % and the content of milk powder 14 %, of which milk fat must be 3.5 %. In the USA the legislation states a minimum of 12 % milk solids of which 3.39 % must be fat. The dried milk products employed must not contain any antiseptic substances or preservatives. In Europe as well as sucrose other sugars such as glucose and lactose can be used.
3) *Household milk chocolates* (called family milk chocolate in UK and Ireland) have a milk content with a minimum of 20 % of which as least 5 % must be milk fat. The proportion of cocoa may be lower, with a minimum of 20 % dry cocoa solids being permitted. Both types of milk chocolate must have a total fat content above 25 %. Limits are also set on the amounts of emulsifier (usually lecithin).
4) *White chocolates* (or cocoa butter confectionery) are mixtures of milk powder, sucrose, and cocoa butter. The proportion of cocoa butter must be a minimum of 20 % and that of milk powder 14 %, 3.5 % of which is milk fat. The total fat content must be a minimum of 25 %.

The chocolates mentioned above may contain additions of dried fruits, hazelnuts, almonds, walnuts, pistachios, pine kernels, etc., either whole or chopped. Filled chocolates are products which contain a solid, plastic, or liquid filling. In many countries special vegetable fats are added in order to modify texture or provide added heat resistance in hot climates. As long as less than 5 % is used, the product can still be called chocolate, although the packaging must clearly state that the product contains vegetable fat.

2. Historical

The cocoa tree originated in the northern part of South America. It was already being cultivated in Central America at the beginning of the 12th century, and was known in Mexico long before the arrival of Christopher Columbus. Cocoa was held in high regard by some of the peoples and was used both as a food and as a currency. Some of the taxes and tributes were paid in cocoa beans. Cocoa beans were a versatile resource during wars when they served as either money or food, depending on the immediate need. When Fernando Cortez conquered Mexico, he discovered large stores of cocoa beans in Montezuma's royal palace. The Spaniards soon learned to prepare a thick beverage, called chocolatl, from roasted cocoa beans, water, maize, and other ingredients along with such seasonings as Spanish pepper, vanilla, and cinnamon.

Columbus introduced this cocoa beverage to Spain, where it was initially received with little acclaim. The Spaniards began to cultivate sugar cane in the newly discovered American territories and soon recognized that the addition of sugar to the cocoa mass considerably improved the taste of the beverage. Chocolate made from cocoa products probably became known in France at the beginning of the 17th century, when it was introduced by Jews expelled from Spain. Between 1606 and 1640, cocoa beans became known in Italy, Holland, England, Germany, and Switzerland, even before coffee and tea. Initially chocolate was a luxury item. Chocolate making developed into a craft in the 18th century, but the processing of cocoa beans still closely resembled the old Mexican method. The cocoa kernels

were ground with a hand roller on a heated stone slab [4, 5].

Commercial production reduced prices and the sweet delicacies became widely accessible. In the 19th century, large factories mechanically producing chocolate rapidly increased the supply.

In Holland, Conrad van Houten improved drinking chocolate in 1828 by pressing out part of the fat from the cocoa mass and grinding the resultant cocoa press cake into a powder. Milk chocolate was invented by Daniel Peter in Switzerland in 1876. Rodolph Lindt invented a method for making chocolate taste smother. In 1879 he began to process chocolate in a machine, called a conche because of its form (Fig. 1). In the conche, chocolate was stirred in a reciprocating manner for several days. Heat, caused by the internal friction, drove off volatile substances with the moisture. External heat was only applied when conching was interrupted to avoid cooling of the mass. During the final phase, pieces of cocoa butter were added. These melted gradually and coated the nonfat constituents, producing chocolate with a pleasant taste, which melted rapidly in the mouth.

3. Raw Materials

The cocoa tree *Theobroma cacao* is cultivated today in tropical rain forest areas around the world, i.e., within 20° north and south of the equator. In warm and humid areas, it grows commercially up to altitudes of 600 m [6].

Most areas of cultivation produce two crops a year: a main crop with high yield and good quality and a second crop of lower yield and quality. The time of harvest depends on climatic conditions. Each tree produces 20 – 30, and sometimes as many as 50, pods, 10 – 35 cm long and 7 – 10 cm wide. Each pod contains 20 – 50 flat, oval beans which are ca. 2 cm long and ca. 1.5 cm wide and weigh ca. 1 g each when dried (Fig. 2). The cocoa bean is surrounded by a thin shell and contains two cotyledons (nibs). Embedded between these is the germ, which is 5 mm long and 1 mm wide.

Cocoa pods must be harvested when fully mature but not overripe; the beans are then fermented and dried. Cocoa pods must be carefully cut from the trunk and branches to avoid damaging the flower cushions.

The yield of fermented and dried cocoa beans per tree is normally 0.5 – 2.0 kg, with a maximum of 4 kg. The useful life of a cocoa tree is ca. 40 years [6]. Cocoa trees are of three basic types, Criollo (native to Spanish America), Forastero (foreign), and Trinitario, usually regarded as a hybridization between Forastero and Criollo trees.

Criollo Cocoa. The pods are elongated with a diameter less than half of the length. The husk shows five deep furrows and five shallow furrows. Its surface is warty and the wall is relatively soft. Criollo trees are very sensitive to external influences such as wind, temperature, dryness, and pests. They produce beans of superior quality but in low yield.

Forastero Cocoa. The pods are rounder; i.e., the diameter is more than half of the length. The hard, smooth wall of the husk has either indistinct longitudinal furrows or none at all. Forastero cocoa trees are robust and produce high yields, but the beans are of lower quality.

Trinitario Cocoa. The pods have a range of shapes and sizes and are often reddish in color. The beans are sometimes colored as those of Criollo. Trinitario beans have the strong flavors of Forastero cocoa, with additional notes, which may be fruity, caramel, or spicy in nature. The trees are higher yielding than Criollo and are the major source of fine flavor beans.

Pests and Diseases of the Cocoa Tree. Cocoa trees in plantations are vulnerable to an attack by pests and diseases [6]. The output of an entire country may suffer as a consequence and the diminished supply may drive the price up.

Figure 2. Cocoa plantation (A), cross-section of a cocoa pod (10 – 35 cm long) (B), and depiction of a cocoa tree with a pod cut open (C)

Black pod disease (Phytophthora) is more or less widespread in almost every cocoa-growing country. It can attack the fruit to cause the pods to rot or the trunk and branches to cause cocoa canker. The Phytophthora fungi produce spores which are spread by rain or insects. Infected pods cause far more damage than infected tree trunks and branches. The fungus develops particularly well in very humid areas of cultivation with high precipitation and relatively low temperatures such as Costa Rica, Nigeria, and Cameroon, and can cause losses of up to 50 %. Fungicides and prompt removal of infected pods help control this disease.

Witches' broom disease causes broom-like growths and deformities. These shoots are thicker than the healthy ones and carry many short laterals with underdeveloped leaves. This disease has caused considerable damage in Brazil, Surinam, Trinidad, Ecuador, Columbia, Grenada, and Venezuela. Cutting out and burning the affected shoots reduces loss.

Swollen-shoot disease has caused serious damage in West Africa, mainly Ghana. It is caused by a virus spread by insects. The virus infection can be lethal, and infected trees should be removed and burned.

Insect Pests. The most destructive insect pests are the capsids (*Sahlbergella singularis, Distantiella theobroma,* and *Helopeltis*). They deposit their eggs in the pods, fruit stems, and branches. Both the insects and their young feed on the cocoa plant tissue. Insecticides are effective against capsids, but they can also damage young cocoa plants.

4. Fermentation and Drying

The harvested cocoa pods are broken carefully using a machete or wooden club. The seed mass is removed by hand.

Fermentation facilitates the separation of the cocoa bean from the pulp, destroys its viability, and forms the flavor precursors in the cocoa cotyledons (nibs).

Heap Fermentation. The cocoa beans removed from the pods are heaped on banana leaves and covered with more leaves. The beans are turned and mixed after 48 – 96 h and then recovered, depending on the progress of the fermentation. Complete fermentation requires about 5 d and is followed by sun-drying.

Box Fermentation. The cocoa beans are placed in containers of wood or (less often) concrete, turned with a shovel every 1 – 2 d and subsequently dried. The complete fermentation process, including drying, normally takes 5 – 7 d.

Basket Fermentation. The cocoa beans are placed in leaf-lined baskets and mixed by transfer into other baskets.

Fermentation juice can drain from the basket, and the cocoa beans are thoroughly fermented.

Criollo beans require 2 – 3 d for fermentation, whereas Forastero varieties require 5 – 7 d. The fermentation yield (i.e., recovery of dried beans) is 31 – 46 % if the residual moisture content is 6 – 8 % (after drying). The fermentation time of Trinitario is very variable, depending on the country where it is grown.

Drying. Fermented cocoa beans contain ca. 60 % water. This must be reduced to less than 7 % to obtain produce of commercial quality. The fermented beans can be sun-dried directly on concrete terraces, on bamboo mats, or on mobile drying racks. In some countries beans are dried using hot air, which is heated artificially. Care must be taken to ensure that smoke does not come in contact with the beans, otherwise the beans take up a smoky flavor and become unusable. Drying must proceed slowly to avoid case hardening and to allow the volatile acids to escape. Drying requires 6 – 7 d, depending on weather conditions, or at least 14 h under artificial conditions. The flavor development continues throughout the drying process.

Chemical and Biological Processes [7 – 9]. Correct fermentation is essential to produce a good chocolate flavor in the final chocolate. Although not imparting the actual flavor itself fermentation does give the chemical precursors, which are later developed at the roasting and conching processing stages. During fermentation the pulp surrounding the beans undergoes an ethanolic, acetic, and lactic acid fermentation. The acid and heat kill the beans, change the cell membranes and facilitates enzyme reactions. The actual flavors and colors produced depend upon the type of bean and fermentation used.

In early fermentation the major saccharide present is sucrose, but this is soon hydrolyzed into glucose and fructose. These sugars are capable of reacting with amino compounds and are therefore very important flavor precursors.

In addition numerous nitrogen-containing precursors are formed including amino acids and peptides.

During the last stages of fermentation oxygen-mediated reactions take place, including the oxidation of protein – polyphenol complexes, which had been formed earlier. This results in a decrease in the bitterness and astringency of the cocoa [6].

A wide range of microbiological flora is present on the beans, ranging from lactic bacteria, to bacillus, yeasts, and molds [7].

The lactic bacteria are important in developing some of the acidic flavors, sometimes required for certain chocolate. Other flora such as molds are able to produce lipases, which will cause off-flavors following the subsequent cocoa powder or chocolate production.

5. Composition of the Fermented Cocoa Bean

There are normally 90 – 100 beans per 100 g of cocoa, depending upon the variety and origin [10]. The proportion of shell is normally 12 – 15 % [11]. The composition of the fermented and dried cotyledons (nibs and broken nibs) depends upon the variety, country of origin, climatic conditions, and time of the harvest. Table 1 shows the average compositions of broken nibs, husks, and germ.

6. Chocolate Production [4, 12]

Cocoa is processed in three stages: preparation of cocoa mass and cocoa powder, preparation of cocoa butter, and manufacture of chocolate. Figure 3 is a flow diagram of the production processes.

6.1. Cocoa Bean Processing

Storage. Cocoa beans are stored in 60 – 65-kg jute or burlap sacks or in silos, or in bin/bays where up to several thousand tons may be stored.

Cleaning. Fermented and dried cocoa beans frequently contain dust, sand, stones, iron, wood, glass, leather, rope, etc. These impurities must be removed before processing, as combustion gas from some of these impurities is particularly detrimental to cocoa flavor, whilst others are very hard and may damage subsequent grinding equipment.

Thermal Pretreatment of Cocoa Beans. To fully develop the flavor, the cocoa beans must be roasted. This can be carried out on the complete beans, on the cocoa nib, or on the liquid

Figure 3. Flow chart for the preparation of cocoa powder and chocolate
* Optional.
** Posttreatment is necessary only if the finely fragmented nibs have received no preliminary treatment.

Table 1. Average compositions of cocoa broken nibs, shell, and germ [4]

Component	Proportion, %		
	Broken nibs	Shell	Germ
Moisture	5.0	4.5	8.5

cocoa mass. For the latter two processes, the shell must be removed before roasting. As the raw beans have their shells tightly attached to the cotyledons, some form of thermal pretreatment is required to aid the separation. This can be done batchwise or by a continuous process. In the latter case the temperature should be $\leq$ 110 °C and the relative humidity $\geq$ 3.5 %. In the micronizing process [13, 14], infrared radiation heats only the surface of the bean to a high temperature. This incinerates pests and destroys insect fragments. It also detaches the cotyledons from the shell without significantly reducing their moisture content. This pre-roasting separation has the advantage that it minimizes the migration of cocoa butter into the shell. With whole bean roasting a significant amount of migration takes place and this cocoa butter is then thrown away with the shell. Immediately following thermal treatment with either steam or infrared radiation, cocoa beans can be broken while still warm. This improves the yield of broken nibs. Because of the increasing demand for products with a low microbiological count, some companies employ a debacterization process, irrespective of the type of roasting process used. This subjects the beans to a thermal pretreatment under high humidity.

Breaking of Beans and Separation of the Shell. Following thermal pretreatment of the cocoa beans or, in the case of the one-stage process, following the roasting of the beans, the latter are broken and the shell and some of the germ are separated from the broken nibs as completely as possible. Cocoa bean shell is extremely hard and often has sand adhering to it. Both of these materials will severely damage any subsequent milling equipment. A good separation of the shell is, therefore, of the utmost importance. The separation, known as winnowing, can be carried out because the shell is in a platelet form, which can rise in an air stream, whereas the heavier "round" nib particles will fall. A modern cocoa bean breaking and winnowing plant is shown in Figure 4.

In the first screening unit, any broken beans are separated in the drum sifter to reduce (a) the load on the impact smasher (b) and the formation of fines. The broken beans (nibs) are conveyed directly to the oscillating sieves (c). The unbroken beans pass through the impact smasher, where they are hurled singly at high speed against radially arranged exchangeable impact plates to produce a minimum of fines pieces. The mixture consisting of broken nibs and shell is then separated by the oscillating sieves (c); the shell is removed and the unbroken beans returned to (b) via (d). The exhaust air is cleaned in the cyclonic separators (e) and the dust filter (g). Coarse or finely fragmented nibs can either be subjected to alkalization for the production of cocoa butter and cocoa powder or can be ground into cocoa mass.

Alkalization of Cocoa Nibs. Coarse and finely fragmented cocoa beans contain butter, starch and other constituents that are for the

Figure 4. Equipment for breaking cocoa beans and winnowing (separating) out shells [15]

most part still enclosed within their cells. The fine nib fragments have a particle size of 1 – 4 mm and are more uniform than cocoa beans in this respect. Chemical treatment, therefore, begins with these particles. For cocoa powder production the nibs are normally treated with alkaline solutions.

As distinct from cocoa mass, in which fat-free cocoa particles are embedded in a continuous phase consisting of cocoa butter, the reaction solution that forms the continuous phase around the broken nibs has unimpeded access to the cocoa constituents with which it can freely react [16, 17]. Subsequent to the reaction, the steam-volatile substances can be removed without hindrance because there is no inhibiting fat layer as in the case of cocoa mass. When cocoa mass is treated, the aqueous reagent solution must diffuse across the hydrophobic fat cover. The adsorption of unpleasant smell- and taste-carrying substances by the cocoa butter and the cocoa starch during drying is then unavoidable [16, 17].

After the reaction, the finely broken nibs are dried and subjected to roasting. This process develops the color and flavor constituents and ensures the destruction of microorganisms, molds, and yeasts.

Grinding of Cocoa Nibs. Cocoa nibs are always ground into a fine cocoa mass. This process is usually carried out in two stages. Pregrinding is performed using cutter or beater blade mills. The nibs are liquefied by cocoa butter, melting during this grinding process. The liquid mass is further refined by roll refiners, ball mills, or disk mills. The cells within the nib must be completely opened up to release the cocoa butter. In general, the finer the cocoa mass is ground, the lower will be its viscosity. Eventually, there is no more fat to release and additional grinding only produces more fine particles which increase the viscosity once again, as is shown in Figure 5. Equipment for grinding nibs and refining cocoa liquor is shown in Fig. 6.

Figure 5. Viscosity of cocoa mass following milling by a three-roll refiner (apparent viscosity at 24 s^{-1} shear rate) after each refiner

Figure 6. Equipment for grinding nibs and refining cocoa liquor [15]
a) Intake; b) Impact and shear mill; c) Homogenizer; d) Pump; e) Three-roller liquor refiner; f) Liquefier

Treatment of Cocoa Mass [12]**.** Because cocoa mass is a homogeneous liquid at temperatures above 40 °C, it can be roasted uniformly or treated by an alkalizing solution. As was noted earlier, some authors believe that this is not as satisfactory as alkalizing the nibs, because the water repellent fat layers inhibit the wetting of the solid cocoa particles [16, 17].

If cocoa mass is roasted, flavor can be developed by a suitable thin-layer heat exchanger treatment.

Quality Determination. The flavor index [17] (Fig. 7) can be used to determine damage caused by incorrect thermal treatment at any of the processing stages.

Figure 7. Extinction curves for the determination of the flavor index in cocoa masses [17]
a) Raw cocoa mass; b) Correctly treated cocoa mass; c) Thermally damaged cocoa mass

In order to determine the flavor index the sample is distilled with steam. The extinction of the distillate is measured between 230 and 300 nm with water as described in [17].

6.2. Preparation of Cocoa Powder and Cocoa Butter

Cocoa Powder. Cocoa powder can be made from cocoa mass prepared from cocoa beans that have only been roasted. However, to provide an attractive color and good suspension characteristics in milk or other aqueous solutions, cocoa powder is usually made from alkalized cocoa mass.

Powdered products are made from cocoa mass partially defatted by pressing out some cocoa butter. Modern presses consist of single pots placed side by side. The base of each pot is an exchangeable stainless steel mesh.

The finely ground hot cocoa mass is fed into the press chamber and partially defatted by driving in steel rams, producing a pressure of typically 40 – 50 MPa.

The cocoa press cakes are ejected automatically, fall onto a conveyor band system, and are transported to air-cooled bins. They contain 8 – 24 % fat. The cooled press cakes are broken up by counter-rotating spiked rollers. Figure 8 is a diagram of a pulverizing and sifting plant.

Figure 8. Preparation of cocoa powder [15]
a) Broken cocoa press cake inlet; b) Broken cocoa press cake milling unit; c) Cocoa powder refrigeration unit; d) Cocoa powder cyclone separator; e) Fan; f) Air and cocoa dust cooler; g) To cocoa powder bagging unit

Cocoa powder is widely used as an intermediate product in the food industry for producing fillings, coatings, desserts, ice creams, cocoa and chocolate beverages, etc. Chocolate flavored coatings may be produced by using low fat cocoa powder and a lauric fat (i.e., palm kernel oil or coconut oil that contain high proportions of short-chain fatty acids, e.g., lauric acid) to replace the cocoa mass.

Cocoa Butter. Cocoa butter pressed from the cocoa mass is collected as a pale yellow oil. To prevent the formation of hard layers, which slow the filtration, the ram pressure must be applied gradually. To obtain cocoa powder with about 21 – 22 % fat, about 50 % of the cocoa butter must be pressed out of the cocoa mass. Highly defatted powders require the removal of even more fat.

Continuously operated expeller presses are used to obtain cocoa butter from whole cocoa beans or from low-quality or impaired cocoa beans. Expeller press cakes can either be used as animal feed, or the residual fat can be extracted with a solvent. Expeller fat is of inferior quality compared with cocoa butter pressed from cocoa mass and must be filtered to remove cloudiness.

The demand for cocoa butter with a neutral smell and taste is increasing. Deodorized cocoa butter is produced by steam distillation under vacuum in a batchwise or continuous process.

6.3. Chocolate Production

Chocolate is a mixture of finely pulverized cocoa mass, sugar, cocoa butter, and flavoring substances such as vanillin (chocolate or milk flavors may not be used). Other ingredients, if so declared, may be added either finely ground, e.g., milk powder, and up to 5 % of nuts, coffee pastes, etc., or in coarse pieces, e.g., almonds, nuts, pine kernels, pistachios, raisins, etc.

6.3.1. Basic Chocolate Mass

Mixing and Kneading of Raw Materials. Finely ground cocoa mass, granulated sugar, and part of the cocoa butter are combined in a heavy-duty mixing and kneading machine, e.g., a double-trough mixing unit (Fig. 9). Intensive kneading action produces a homogeneous plasticized mass that can be ground on a roller-refiner. This requires a fat content of 20 – 28 %, depending on the other constituents. For milk chocolate, full-cream milk powder and/or skim milk are also added.

Milling. The most common method of grinding chocolate mass is based on the two-stage process using roll refiners for pre-refining and final refining. Refining breaks the components, wets them with fat, and helps develop the flavor of the basic chocolate mass. A single two-roll refiner (less commonly a three- or a five-roll refiner) is used to pre-refine the ingredients and this is followed by several five-roll refiners operating in parallel, which reduce the solid particles to the final required particle size. The rollers on the refiners are barrel shaped, but become parallel under the high pressures used to crush the chocolate.

Prerefining. Sugar is important because it is a flavor carrier [18]. The chocolate mass that results from grinding crystal sugar and cocoa together is said to be organoleptically superior to that obtained with sugar that has been prerefined on its own. The crushing/shearing action also coats some of the broken particles with fat. Crushing the particles in two stages produces a smaller proportion of very fine particles, than if all the milling was carried out at a single stage, or if the sugar was premilled alone and then added to the other ingredients for roll refining.

Final Refining. Having gone through the prerefiner, the basic chocolate mass is milled to the required final particle size in a five-roll refiner. The rollers are hollow and can be cooled or heated with water. The rolls increase in speed as the chocolate mass passes up the refiner. This

Figure 9. Mixing and two-stage refining system [15]
a) Chocolate mixer; b) Chocolate prerefiner; c) Conveyor (prerefined chocolate); d) Chocolate fine-refiners; e) Conveyor (refined chocolate)

causes the film of material between the rolls to become thinner and each subsequent gap between the rolls to decrease. The final fineness is largely controlled by adjusting the gap between the first two rolls, manipulating the roll temperature and by changing the relative speeds of the rolls. As with the two-roll refiner, the shearing action coats some of the solid particles with fat. A knife scrapes a thin film of chocolate powder or flakes from the fifth roll and conveys it to the final texture- and flavor-developing process (Fig. 10). The specific surface area of the nonfat constituents grows rapidly with increasing fineness. In addition, the organoleptic properties of the chocolate are significantly influenced by its fineness and texture. Top-quality products leave less than 1.5 % of the fat-free chocolate constituents on a 30-µm sieve, or have a 90th percentile of the mass distribution of < 25 µm.

Final Texture and Flavor Development. The basic chocolate mass is obtained after refining as a dry powder or thick paste; it must then be plasticized and liquefied to give the flow properties needed for further processing and to develop the required organoleptic properties. This can be achieved by a number of very different machines (conches) which operate on the kneader or rotation principle. The conching process normally takes place in three stages: (1) dry conching; (2) plasticizing; and (3) liquefying.

Dry Conching. The basic chocolate mass obtained after refining is directly conveyed to a conche, e.g., the Petzholdt High-Speed Texture

Figure 10. Hydraulically controlled five-roll chocolate refiner [15]
a) Hydraulic roller system; b) Hydraulic control; c) Feed; d) Removal of refined mass

and Flavor Developing Machine or the Thouet DRC Dry Conche (Fig. 11). Inner friction raises the temperature steadily, which causes the evaporation of moisture and some volatile flavor

components. The chemical reactions are not completely understood. The volatile substances can be identified by gas chromatography. These are mainly acetaldehyde, acetone, isobutanol, ethanol, isopropanol, ethyl acetate, isopentanol, methanol, and diacetyl, which occur in cocoa in traces. The temperature should not rise too rapidly; otherwise the moisture can not escape from the conche and instead will re-enter the chocolate and cause the sugar to stick together in agglomerates. This in turn gives a gritty tasting chocolate. The dry conching stage may take up to a few hours, the actual time depending on the moisture in the original ingredients and the conche type and temperature. The latter also affects the taste of the chocolate. Very mild flavored chocolates are usually conched below 60 °C, with high temperatures of 80 °C to above 100 °C being used to introduce a cooked flavor.

Plasticizing. Once most of the moisture has been evaporated the plasticization begins. This consist of deagglomeration of the finely ground particles, optimum fat distribution and the surrounding of the nonfat constituents by a film of fat.

Liquefaction. After plasticizing, the chocolate mass is liquefied by the gradual addition of the residual cocoa butter and emulsifier while being subjected to continuous mechanical working. It is normally considered preferable to add the lecithin or other emulsifiers once the chocolate has been cooled below 50 °C. Chocolate mass with optimum flow properties is the end result. The liquefied chocolate is then pumped into storage tanks fitted with agitators.

Storage. In the past, the finished chocolate was poured into trays holding 40 – 50 kg each, turned out after solidifying, and kept in blocks in cooled storage rooms. Although these are still available, nowadays chocolate is often sold as smaller pieces or chips, up to about 2 cm in diameter. However, both cooling and remelting require energy, and melted chocolate masses are now held in large heated tanks, which are provided with agitators, until they are processed further. Because aging reactions accelerate with

rising temperatures, storage of chocolate in liquid form is advisable for short periods only. The temperature must be kept above 40 °C to prevent crystallization of the higher-melting glycerides, which are important for the subsequent precrystallizing (tempering) process, although white chocolate should be stored at lower temperatures. Vertical tanks are provided with agitators to prevent sedimentation of the bigger particles and separation of the fat.

6.3.2. Precrystallization (Tempering) [20, 21]

The precrystallization process (tempering) is of equal importance as the quality of the raw materials, the formulation, and the correct processing of chocolate masses with regard to the keeping qualities, heat resistance, gloss, snap, melting properties, texture, etc. of a chocolate. Cocoa butter can crystallize in six different forms (Fig. 12). Only form V (β_2) will give these desirable properties. If chocolate is made with the less stable forms, not only will it not contract properly (because the crystals are not so compact), but it will rapidly change its form, pushing fat to the surface. This gives a white mold-like appearance known as chocolate bloom.

Figure 12. Different crystal forms of coca butter as a function of temperature

During the solidification of the melted chocolate mass, the fat phase must build a structure that consists of these type V (β_2) crystals throughout. Tempering is, therefore, the most important factor in the entire solidification process.

A large number of crystals of the correct type must be distributed throughout the chocolate. This must be done rapidly in order to meet with the needs of the chocolate usage plants. Cooling cocoa butter to 32 °C would take many hours to reach this state, and so alternative methods must be used. The most commonly used tempering procedure is to cool the chocolate much further, so as to produce a lot of both stable and unstable crystals (Fig. 13). The chocolate is then reheated to melt the unstable ones. The process takes place inside a rapidly rotating machine, which breaks up the larger crystals and distributes the resulting smaller ones throughout the chocolate.

The degree to which a chocolate mass is tempered can be evaluated by means of a tempering diagram. This is obtained by rapidly cooling a small quantity of chocolate and measuring its temperature as it sets. Figure 14 A shows a tempered sample, which cools slowly, because the latent heat of solidification comes out quickly and matches the cooling. The chocolate then sets rapidly. Figure 14 B shows a lightly tempered chocolate, which cools slowly and even reheats, but sets more slowly than that in Figure 14 A. The sample in Figure 14 C is untempered and will take a very long time to set and does not contract properly.

6.3.3. Processing Precrystallized Chocolate

The precrystallized chocolate mass can be used for molding and enrobing. Both cases require correct precrystallization, followed by careful cooling. Too fast a cooling rate may result in the wrong types of crystals being formed.

Molding. The molding process permits the preparation not only of blocks, bars, or single pieces with or without the addition of coarsely chopped nuts, raisins, croquants, etc., but also of products with a solid or liquid center completely enclosed in chocolate.

Solid products are made by dosing the precrystallized chocolate, with or without coarsely chopped additions, into molds where it is distributed in the mold by vibration and scraping. It is subsequently cooled and demolded. The preparation of filled chocolate bars and chocolates requires more complex equipment.

The hollow chocolate shells are usually made by first of all filling the molds as for the solids bars. The chocolate is allowed to partially set before the mold is inverted and the central liquid chocolate allowed to run out. The center filling,

Figure 13. Milk chocolate tempering sequence (Reprinted with the permission of Loders Croklaan)

Figure 14. Cooling curves of tempered (A); lightly tempered (B); and untempered chocolate (C)

e.g., praline, fondant, or caramel is then poured in, before a coating of liquid chocolate is used to complete the shell.

Enrobing. The centers to be enrobed (e.g., nuts, marzipan, wafers, etc.) are heated to a slightly lower temperature than that of the tempered chocolate, before being placed on a wire grid conveyor belt. This transports them through one or two curtains of tempered chocolate (see Fig. 15). The product is then subjected to vibration and being blown in an air curtain, which removes the excess chocolate and gives the required weight. The excess chocolate falls through the wire grid to be recirculated onto another batch of centers. Once again careful cooling is required. Where the center is very rough or a thick layer of chocolate is required, two enrobers may be used, before the product is cooled.

7. Other Chocolate Processes

Crumb Process [22]. Crumb originated in the 1930s when milk powder had poor keeping properties. By drying the milk together with the sugar and cocoa mass (which contains natural antioxidants) a chocolate making ingredient was developed, which has a long shelf-life. The milk is partly evaporated, mixed with a 60 % sugar solution, and concentrated to a form that is 87 – 90 % dry solids. The cocoa mass or cocoa powder is then added and, after being dried to a residual moisture content of ca. 2 %, the crumb is pulverized. The proportion of cocoa mass is 6 – 12 %.

Figure 15. Chocolate enrober

To produce milk chocolate, the crumb powder requires only the addition of cocoa butter, flavors, and lecithin. The flavors of the cocoa are readily absorbed by the milk crumb because the carbohydrates, sucrose and lactose, in many crumb making processes are present predominantly in an amorphous form and only subsequently become crystalline. The proteins are also distributed in the crumb in a colloidal form. The crumb powder is worked in heavy-duty mixing and kneading machines while cocoa butter and flavorings are added. The resulting mass is then roll refined and then conched as for chocolates manufactured from milk powders. Sometimes the conching time is shortened, however, because some of the flavor changes, in particular cooked Maillard type notes, have already been developed during the crumb making process.

Low Calorie Chocolate. As with many other foods, there has been a demand in many of the developed countries for low calorie or low fat products.

One of the most widely used methods of reducing the calorific value of chocolate is to replace the sugar by sugar alcohols such a maltitol or lactitol together with some polydextrose. The sugar alcohols often form agglomerates and become gritty at higher conching temperatures, so some care has to be taken in processing them. In addition they must be eaten in limited amounts due to their laxative effects. Polydextrose has a lower calorific value than the sugar alcohols, but tends to give a drying effect in the mouth.

Another way to reduce the calorific value is to use a low calorie fat such as Benefat [23]. This is only permitted in a few countries, and because the fat is not very compatible with cocoa butter, the chocolate must normally be manufactured from cocoa powder.

The calorific value can also be reduced by lowering the fat content. However, it is necessary to maintain a viscosity similar to that of standard chocolate in order to enable processing, and to obtain satisfactory eating properties. Maintenance of viscosity is normally achieved by modifying the particle size distribution to have less surface of solid particles to coat with fat; by increasing levels and modifying types of emulsifiers; and by improved mixing/conching machinery [24].

Heat-Resistant Chocolate [25]**.** There are four processes which can be used to make chocolate more heat resistante for sale in hot climates;

1) Modifying the fat phase
2) Heat cycling
3) Adding moisture
4) Building a carbohydrate structure

Modifying the Fat Phase. Milk fat softens chocolate, so this type of fat should be reduced. In addition cocoa butter obtained from cocoa grown nearer the equator is harder to melt than that grown further away. Consequently chocolate made with Malaysian cocoa butter is much more heat resistant than with that obtained from West African, which in turn is better than most Brazilian product. Certain vegetable fats will also make chocolate much more heat resistant, but in many countries the product cannot be sold under the name chocolate. Some of these fats are also very effective at reducing chocolate bloom.

Heat Cycling. By carefully adjusting the temperature of the chocolate before manufacture, or of the finished product, it is possible to improve both heat and bloom resistance. Figure 16 [26] illustrates the use of cyclothermic precrystallization to mold better (dark) chocolate at 35 – 36 °C. Finished product can be improved by heating to 29.5 ± 0.5 °C [27] for 6 h.

Adding Moisture. Water rapidly increases the viscosity of chocolate by sticking together the sugar particles. This makes it very difficult to process the chocolate. A number of ways of getting around this problem have been devised; such as adding the water as an emulsion, or mixing it very rapidly with tempered chocolate just before molding. Another patent describes wrapping the product in a water permeable wrapper and then storing it in a moist atmosphere.

Building a Carbohydrate Structure. This process strengthens the texture of the chocolate. The nonfat substances of conventional chocolates are enveloped by a fat film that liquefies when heated and causes the system to flow. In heat-resistant chocolates, the nonfat substances form a continuous phase and produce a structure by partial adhesion. The fat is enclosed in isolated hollow spaces [22].

One possible method for building a carbohydrate structure is as follows: a sugar solution is made up of, for example, 80 % sucrose and 20 % invert sugar or glucose syrup. This solu-

Figure 16. Temperature program for the cyclothermic preparation of heat-resistant chocolates [26]

tion is concentrated under vacuum to a residual moisture content of 1 – 2 % and cooled from a maximum of 150 °C to ca. 80 °C. This concentrated sugar is made into a homogeneous mixture of ca. 90 % sugar and 10 % butter or other fat (at ca. 150 °C for easy processing). The mixture solidifies when cooled. It is then pulverized to an extremely fine powder in a micronizer mill; the particle size should be <30 µm. Grinding must be carried out at 20 – 25 % relative humidity. The sugar – fat mixture is next homogeneously mixed with a finished bitter chocolate or milk chocolate mass at <50 °C, and the resultant mass is precrystallized, molded, and cooled to 15 ± 1 °C. The chocolate bars are wrapped in aluminum foil immediately after demolding and are hermetically sealed. The wrapped bars must be stored for 30 d at 25 ± 1 °C to allow the sugar structure to develop.

The heat-resistant texture can be tested by immersing pieces of the chocolate in ether for several hours; whereas ordinary chocolate breaks down because the fat phase is dissolved, chocolate with a sugar matrix remains practically unchanged [22].

8. Packaging, Storage, Spoilage, Analysis

Packaging. Chocolate bars and filled chocolates must be packaged in odor-free materials (no odor or taint may come from the material itself, inks, lacquers, or the cold seals applied). Light protection is also required in case of white chocolate. To guarantee the quality of the product over several years, packaging with an oxygen barrier is occasionally required. Aroma barriers are also sometimes necessary, depending on the environment and length of storage of the packaged products.

For chocolate tablets, hermetically sealed lacquered or laminated aluminum foil provides the best protection against the entrance of foreign odors, loss of flavor, and infestation of pests. Good quality foil should be used as thin material with numerous pinholes will not provide good protection. The foil, which is laminated to a heat-sealing film, for example, polypropylene, is heat-sealed and wrapped in a printed sleeve, envelope or carton. Double folds and envelope-type wraps (traditional chocolate tablet packaging, that is not heat-sealed) only offer limited protection. Printed opaque or metallized oriented polypropylene films offer very good protection and are frequently used in the flow wrapping of chocolate bars. These materials are more cost effective than aluminum foil laminates and can also be used to flow wrap chocolate tablets. In this case, however, the traditional appearance of the pack (paper outer envelope wrap with foil inside) is lost.

Table 2. World production of cocoa beans in 2001/02 and 2002/3 in 1000 t [30]

Country	2001/2002	2002/2003*
Côte d'Ivoire	1265	1300
Ghana	341	475
Indonesia	455	440
Nigeria	180	165
Brazil	124	150
Cameroon	126	135

[a] Other countries producing between 25 000 t and 90 000 t are Ecuador, Dominican Republic, Papua New Guinea, Malaysia, Colombia, and Mexico.
* Estimated.

Storage. Cocoa and chocolate products must always be stored in a cool, dry, dark, and odor-free atmosphere. The most suitable condition for extended storage is a temperature of 10 – 18 °C with 55 – 65 % relative humidity. Larger temperature fluctuations are particularly detrimental to product shelf life because fat crystallizes out during cooling and causes contraction. When the temperature is again increased, the liquid proportion of the fat phase increases, causing an increase in volume and a consequent increase in pressure. This "pumping effect" changes the texture and accelerates the aging of cocoa and chocolate products.

Spoilage. The visual damage called *fat bloom* is caused not only by improper precrystallization of the melted chocolate (see Section 6.3.2), but also by excessive heat or by soft fat such as hazelnut oil migrating into the chocolate from the center filling.

Sugar bloom only occurs when the surface of cocoa and chocolate products is wet, e.g., through microcondensation, and the sugar dissolves. On drying, the sugar crystallizes out on the surface in coarse crystals. This happens when the cooling tunnels, used to set the chocolate, are operated below their dew point.

Analysis. The main constituents of cocoa and chocolate products are sugar, cocoa mass, cocoa butter, dry milk solids, lecithin, and vanillin. Of analytical interest are moisture, sugars, fat, proteins, and alkaloids. Specific analytical methods have been published by the International Office of Cocoa, Chocolate and Sugar Confectionery (IOCCC) in Brussels. Appropriate measuring methods have also been developed on an international level for the evaluation of chocolate fineness and the determination of flow properties.

9. Economic Aspects

Cocoa beans are referred to commercially according to either their country of origin, main area of cultivation, or port of dispatch. Cocoa beans from different areas of cultivation differ quite considerably in flavor and organoleptic properties, and this is reflected in their prices. The great trading centers for cocoa beans are in New York and London. Chocolate and cocoa powders are usually produced from mixtures of cocoa beans of different origins and blended according to strictly secret recipes.

The production of cocoa beans in the main growing countries is given in Table 2. Due to changes in the economy in countries such as Nigeria and Malaysia, the production of cocoa has tended to decrease, whilst witches' broom disease has had a devastating effect upon Brazilian production. On the other hand, new plantings in the Côte d'Ivoire and Indonesia have in-

Table 3. Production and consumption figures for the top ten (1996) consumer countries for chocolate confectionery in 2003 (metric tons)

1. Introduction

Choline [*62-49-7*], $C_5H_{15}O_2N$, M_r 121.18, trimethyl (2-hydroxyethyl) ammonium hydroxide was first isolated from pig bile by Stecker in 1849. Later, choline was isolated from brain tissue. Choline is a quaternary ammonium compound that is found in most biological materials:

$$[(CH_3)_3N^+CH_2CH_2OH]\ OH^-$$

Free choline makes up only a small proportion of the total choline found in biological materials. More common forms include phosphorylcholine, phosphatidylcholine (→ Lecithin), and acetylcholine. In addition, choline is associated with the metabolism and synthesis of glycine, betaine, cysteine, serine, methionine, and many other methyl-group-containing biological compounds.

Choline has four primary functions [1]:

1) Structural component of cell membranes in the form of phosphatidylcholine (lecithin) and sphingomyelin,
2) Lipotropic agent in the prevention of fatty liver,
3) Neurotransmitter in the form of acetylcholine, and
4) Source of labile methyl groups.

Choline has been referred to as a vitamin, although from a classical standpoint it is not, since it is not known to function as a cofactor in any enzymatic reaction. Like the vitamins, choline plays a significant role in nutrition but its daily requirement is significantly greater than that of vitamins. The recommended daily intake for humans is given in Table 1.

Table 1. Choline, recommended daily intake [2]

Population	Category	Adequate intake mg/d
Infants	0 – 5 months	125
	6 – 11 months	150
Childrens and adolescents	1 – 3 years	200
	4 – 8 years	250
	9 – 13 years	375
	14 – 18 years	550
males		
	14 – 18 years	400
females		
Adults		
	19 years and older	550
males		
	19 years and older	425
females		
Pregnancy	all ages	450
Lactation	all ages	550

The United States Pharmacopeia is drafting USP monographs for choline chloride and choline bitartrate for inclusion in the second or third supplement of USP 24 in the year 2000 [3].

In growing animals, fatty liver and reduced growth rate are the most common choline deficiency symptoms. Numerous animal species, including rats, mice, puppies, young pigs, calves, guinea pigs, chicks, ducklings, turkey poults, trout, and monkeys, have demonstrated a requirement for choline to produce maximum growth rate and prevent fatty liver [4]. Several salts of choline (chloride, dihydrogen citrate, and bitartrate) are often added to animal feeds as a dietary supplement.

While the nutritional needs of humans and animals dominate the choline industry in both on-going research and industry production of dietary supplements, there are other significant uses for choline. A review of the Chemical Abstracts Chemical Substance Index from

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a07_039

1995 – 1998 revealed six areas of significant patent activity (see Table 2).

Table 2. Industrial patent activity

Industry	Uses	Choline compound
Integrated circuits/semiconductors	cleaning, resist removal, etc.	choline and salts
Printed wire boards	resist removal, developer, etc.	choline and salts
Silica/silicic acid	catalyst in manufacturing	choline salts
Health	antifungal and wound healing	choline salts
Textile	laundering, finishing agent, dyeing, etc.	choline salts and esters
Oil drilling	drilling fluid, soil stabilization	choline salts

2. Properties

Choline is a strong base (pk = 5.06) which absorbs carbon dioxide and water from the air. Choline is usually a colorless, viscous liquid with a fishy odor. The products of commerce are solutions in methanol or water with a concentration of 45 vol % or less. Choline is also soluble in ethanol; hardly soluble in acetone and chloroform; and insoluble in ether, benzene, toluene, and carbon tetrachloride. Choline reacts with acids to form stable salts. Most of the choline salts except the chloride, bitartrate and dihydrogen citrate are difficult to crystallize. Choline also reacts with acids to form esters. Choline, a quaternary ammonium hydroxide, undergoes self-decomposition when it is heated. The reaction, known as the Hoffman Elimination is [5]:

The unstable vinyl alcohol rearranges to acetaldehyde or can react with water to form ethylene glycol. Acetaldehyde can undergo aldol condensation leading to color forming products, while the trimethylamine gives the solution a strong "fishy" odor.

3. Production

Choline is normally produced by the reaction of trimethylamine, ethylene oxide, and water.

Its chloride can be produced by the reaction of trimethylamine with chlorohydrin.

While other syntheses exist, the dominating industrial process is reacting ethylene oxide with trimethylamine and water, or an acid if one of its salts is desired, in a batch or continuous manufacturing process.

4. Analysis

Analytical procedures for choline, until recently, could be characterized as laborious, imprecise and relatively unspecific. Analytical methods for feed include perchloric acid titration [6] and the Reineckate procedure. The Reineckate procedure is used most frequently. Engel first described the Reineckate procedure for choline analysis in 1942. Basically it involves the extraction of choline-containing lipids, formation and separation of a water insoluble Reinecke complex and then spectrophotometric determination of the acetone soluble Reinecke complex at 520 nm. Sensitivity for choline analysis using the Reineckate procedure is as little as 100 ppm in plant and animal tissues.

More recent methods for determining choline rely on enzymatic procedures. Takayama et al. (1977) described a method that was specific for choline in serum. This method offers possible specific determination of choline in animal and plant tissues.

Numerous other enzyme-linked assays, gas, and liquid chromatographic, radiochemical and fluorometric procedures for choline have been described [7].

The perchloric acid method is satisfactory when applied to pure choline and its salts.

5. Economic Aspects

Market requirements for all forms of choline in the animal nutrition, human health, printed wire boards and integrated circuits are closely guarded by industry members. Worldwide uses in animal nutrition are probably $> 30\,000$ t/a while human health, printed wired boards and integrated circuits markets are probably less than 2000 t/a for each industry.

6. Salts

Choline chloride [*67-48-1*], $C_5H_{14}ONCl$, M_r 139.63, white crystalline solid with a slight amine-like odor and a strong brackish taste. It is hygroscopic and decomposes at ca. 180 °C to form dimethylaminoethanol and methyl chloride. Choline chloride is very soluble in water, freely soluble in alcohol, slightly soluble in acetone and chloroform, and almost insoluble in ether and benzene. Its solution is neutral to litmus paper.

Choline hydrogen tartrate [*87-67-2*], $C_9H_{19}O_7N$, M_r 253.26, *mp* 149 – 153 °C, is a white crystalline powder with an acidic taste and a slight amine odor. It is less hygroscopic than other choline salts. It is very soluble in water, slightly soluble in alcohol, and almost insoluble in ether, benzene, and chloroform. The pH of a 25 % aqueous solution is about 3.5.

Choline dihydrogen citrate [*77-91-8*], $C_{11}H_{21}O_8N$, M_r 295.30, *mp* 105 – 107.5 °C is a white granular to fine-crystalline powder with a faint amine-like odor and a acidic taste. It is hygroscopic and very soluble in water, soluble in alcohol and almost insoluble in ether, benzene and chloroform. The pH of a 25 % aqueous solution is about 4.3.

Choline bicarbonate [*78-73-9*], $C_6H_{15}NO_4$, M_r 165.2, its solution is a clear liquid, colorless to slightly yellow with a characteristic amine-like odor. An aqueous solution containing about 75 % choline bicarbonate has a pH between 9.0 and 11.5. Besides being very soluble in water, choline bicarbonate is freely soluble in alcohol and slightly soluble in benzene.

Choline gluconate [*608-59-3*], $C_{11}H_{25}O_8N$, M_r 299.33, is a hygroscopic yellow mass, soluble in water and slightly soluble in ethanol.

7. Uses

Choline deficiency in domestic animals is fairly well characterized and is preventable by the addition of choline salts to the diet. Research in human nutrition has focused on the potential for choline to alleviate various disease conditions. Many of these investigations are in their infancy and should provide further information concerning the function of choline in biological systems. Choline salts, such as the chloride, hydrogen tartrate, dihydrogen citrate and gluconate are used therapeutically for patients with liver cirrhosis that has not advanced to the irreversible fibrous stage. Oral choline does appear to be effective in reversing fatty infiltration and arresting the cirrhosis process. Common therapy includes the use of a low fat, high protein, high calorie diet with the usual vitamins and choline [8]. Orally, choline salts are used to provide the recommended dietary intake of choline for humans. Acetylcholine [*51-84-3*] is used as a vasodilator. Methacholine chloride [*62-51-1*], (*O*-acetyl-β-methylcholine chloride) is used as a parasympathetic stimulant and as an antiepinephrine substance. Carbamoylcholine chloride [*51-83-2*] is used to increase peripheral circulation in cases of vasospasms caused by peripheral vascular disorders.

The food and cosmetic industry has had an increasing interest in choline, brought about by the demand for harmless surface-active agents. Some acylcholine compounds, such as stearoylcholine chloride, have been suggested as ingredients in hair conditioners [9]. Chlorocholine chloride [*999-81-5*], (2-chloroethyltrimethylammonium chloride) is used as a plant growth regulator to maintain the compactness of the plant [10] as opposed to the growth-accelerating effects of gibberellic acid. It is used for ornamental plants, especially poinsettias and azaleas. It is also used to prevent the lodging and flattening of wheat by wind, as well as the etiolation of greenhouse tomatoes, thus leading to earlier and larger fruit yields [11].

8. Toxicology

Choline has a low toxicity. An acute toxicity test of choline chloride administered orally to rats shows an LD_{50} value of 3 – 6 g/kg [12]. Because of its high basicity choline is classified as corrosive.

1. Chromium

1.1. History [1–5]

Chromium [*7440-47-3*], Cr, A_r 51.9961, was discovered by Vauquelin, in the mineral crocoite [*14654-05-8*], $PbCrO_4$, in 1797. In 1798 he isolated chromium metal by reducing the oxide with carbon. Soon after the discovery of chromium, the commercial process for manufacturing chromates by roasting chromite with soda ash was developed.

During the 19th century, ferrochromium and chromium were produced by a variety of techniques. However, a commercial process was not developed until 1893, when Moissan produced ferrochromium in an electric furnace by the reaction of chromium oxide (Cr_2O_3) and carbon. In 1898, Goldschmidt produced chromium by the aluminothermic reduction of Cr_2O_3. Other advances have included the application of silicothermics to the production of low-carbon ferrochromium and chromium, production of chromium by aqueous electrolysis, and production of low-carbon ferrochromium and refining of electrolytic chromium by high-temperature vacuum processing.

Although Cr is found in many minerals, chromite is the only commercial source of Cr. Most of the mineral came from the Ural Mountains up to 1827, when deposits were discovered in the United States. These supplied a limited market up to about 1860, when large deposits were found in Turkey. Since that time chromite has been mined primarily in the eastern hemisphere.

Chromium was electrolyzed from a solution of chromium chloride by Bunsen in 1854. However, large-scale commercial production of electrolytic Cr did not begin until 1954.

1.2. Chemical and Physical Properties [6], [7], [8]

At room temperature Cr is resistant to ordinary corrosive agents, which explains its use as an electroplated, protective coating. It dissolves in nonoxidizing mineral acids, such as hydrochloric and sulfuric acids, but not in cold aqua regia or nitric acid, which passivate the metal. At elevated temperature it reacts with halogens, silicon, boron, nitrogen, oxygen, and carbon.

Chromium and chromium-rich alloys are brittle at room temperature and this has limited their application [9].

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Selected physical properties of chromium are as follows:

A_r	51.9961
Atomic number	24
mp	1857 °C
bp	2672 °C
Density ϱ at 20 °C	7.19 g/cm^3
Crystal structure	cubic, body centered
Specific heat at 25 °C	23.25 J mol^{-1} K^{-1}
Molar entropy S°_{298}	23.64 J mol^{-1} K^{-1}
Heat of fusion	16.93 kJ/mol
Latent heat of vaporization at *bp*	344.3 kJ/mol
Linear coefficient of thermal expansion at 20 °C	6.2×10^{-6}
Resistivity at 20 °C	12.9×10^{-8} Ω m
Thermal conductivity at 20 °C	67 W m^{-1} K^{-1}

1.3. Resources and Raw Materials [4]

Chromite [*53293-42-8*] is a spinel $FeO \cdot Cr_2O_3$. In nature it is a mixture described by the formula $(Fe^{2+}, Mg)O \cdot (Cr, Al, Fe^{3+})_2O_3$. Chromite ore rarely contains more than 50 % Cr_2O_3; other minerals such as SiO_2 can also be present.

Chromite is found in stratiform and podiform deposits. Stratiform deposits occur in layers up to a meter thick. The Bushweld Igneous Complex (Transvaal, Republic of South Africa), the Great Dyke (Zimbabwe) and the Stillwater Complex (Montana, United States) are examples. Podiform deposits range in size but a typical commercial deposit will be over 100 000 t. Deposits occur in the Ural Mountains, Albania, Zimbabwe, and the Philippines.

The 1983 production and reserves of chromite are shown in Table 1 (see right). Generally, richer lumpy Cr bearing ores have been preferred for smelting, whereas those with Cr_2O_3 content less than 40 % have been used in refractories. For a detailed discussion of chromium ores, see → Chromium Compounds.

1.4. Production

Extraction. Chromium is extracted from its ores by alkaline or acidic dissolution. In alkali dissolution, finely ground chrome ore is roasted with Na_2CO_3 under oxidizing conditions at ca. 1100 °C. The sodium chromate is leached from the calcine; most of the gangue is insoluble. The solution containing hexavalent Cr can be reduced with SO_2 and used for electrowinning, or $Na_2Cr_2O_7$ can be crystallized from it. The $Na_2Cr_2O_7$ can be converted to CrO_3 for use in electrolysis or to Cr_2O_3 for use in metallothermics.

Chrome ore can be dissolved in acid if an oxidizing agent is present. However, Fe, Al, and Mg also dissolve and must be removed. The preferred acidic dissolution technique is to reduce the ore with carbon, forming ferrochromium, which is ground and dissolved in sulfuric acid. The only significant impurity carried over is Fe, which is removed by crystallization as iron(II) ammonium sulfate. The Cr in the solution is in the +3 valence state and with additional purification is used to produce electrolytic Cr.

[b] Shipping grade ore is deposit quantity and grade normalized to 45 % Cr_2O_3 for high-Cr and high-Fe chromite, and 35 % Cr_2O_3 for high-alumina chromite.
[c] Reserve base includes deposits currently economic (reserves), marginally economic, and some currently subeconomic.

Production of Chromium Metal. Chromium metal is produced by the reduction of Cr_2O_3 or the electrolysis of Cr(III) solutions. The metal can also be obtained from Cr(VI) solutions by electrolysis, but the process is less efficient and is used primarily for plating.

Aluminothermic Reduction. Aluminum is the most important reducing agent for producing Cr from Cr_2O_3. Closely sized high-purity Al powder and Cr_2O_3 are blended and charged into a vessel lined with refractory, which is usually Al_2O_3. The charge is ignited either with a $KClO_4$– Al powder "wick" or electrically. The

Figure 1. Flow sheet for producing electrolytic chromium from ferrochromium [10]

exothermic reaction results in a temperature greater than 2000 °C, which leads to a clean separation of slag from metal. The purity of the Cr metal depends on the purity of the reactants, particularly the Cr_2O_3. Originally this oxide was made by reduction of sodium chromate with sulfur, resulting in Cr_2O_3 of high sulfur content. Proprietary processes have been developed to produce Cr_2O_3 of higher purity. Analysis of aluminothermically reduced Cr is given in Table 2.

Chromium is also produced by *carbon reduction.* Chromium oxide and carbon are carefully weighed, mixed, briquetted, and heated in a furnace at 1400 °C at a minimum pressure of 40 Pa. The heating cycle is 100 h. The C + O content is $\leqq$ 1.5 % (see Table 2).

Solutions suitable for *electrolytic production* of Cr can be derived from ore by oxidative roasting in alkali, or by direct solution of chromite in sulfuric acid; however, a commercial process was not achieved until the electrolyte was made by dissolving ferrochromium in H_2SO_4 and reduced anolyte. Figure 1 (see previous page) [10] shows the essential aspects of the process for electrolytic production of chromium metal.

Milled FeCr is leached with hot reduced recycled anolyte, chrome alum mother liquor, and makeup H_2SO_4. The iron precipitates on cooling as iron(II) ammonium sulfate $[Fe(NH_4)_2(SO_4)_2]$, which is recrystallized to recover the coprecipitated Cr.

The Cr is further purified by precipitation of chrome alum. Transformation of the Cr(III) to an insoluble salt requires aging at 30 °C. After filtration the mother liquor is recirculated to the leach tank. The chrome alum crystals are redissolved to make the cathode feed. The overflow anolyte contains Cr(VI), which is reduced by SO_2, thereby generating additional H_2SO_4. The reduced anolyte is also cycled to the leach tank. The stripped catholyte is recycled. Dissolved chrome alum crystals are used to bring the Cr concentration in the catholyte feed up to the desired level.

The details of the *cell reactions* are shown in Figure 2 (see next page) [11]. A diaphragm is necessary to prevent migration of Cr(VI) into the cathode compartment where its reduction by Cr(II) would lead to loss of current efficiency. Flow is maintained into the anode compartment from the cathode compartment by a higher level of solution in the latter. The pH of the catholyte must be controlled. At too low a value, H_2 evolution increases; at too high a value, precipitation of $Cr(OH)_3$ occurs. This can be seen by an examination of the pH – potential diagram [12]. The pH is controlled by Cr concentration, current density, temperature, and differential height of solution between cathode and anode compartments. Water is fed to the anode to control the concentration of H_2SO_4.

Chromium is plated onto stainless steel cathodes until it attains a thickness of ca. 3 mm. The plate is stripped from the cathode and degassed by heating at 420 °C. The analysis of the flake is shown in Table 2.

For many applications the oxygen content of the electrolytic chromium is too high. Deoxidation is carried out on a commercial scale by two techniques [13]. In the first either flake or briquettes of powdered flake are contacted with H_2 at elevated temperature. The procedure is less effective on Cr produced from chrome alum solutions than on Cr from hexavalent solutions [14]. The second technique involves heating briquettes of ground electrolytic flake and carefully controlled trace amounts of C in a vacuum furnace to form CO. The heating cycle is 90 h, the maximum temperature is 1400 °C, and the pressure is 13 Pa. The product is cooled in helium to

prevent contamination. Analysis of the vacuum-treated product is shown in Table 2.

There are several other techniques for purifying Cr. These include iodide refining [9], [14], zone melting [9], [14], and treating Cr with a flux containing an alkaline earth metal [15]. Chromium prepared by these methods is purer but more expensive, and therefore is used only in electronic applications.

1.5. Uses [4]

Chromium is used in ferrous and nonferrous alloys, in refractories, and in chemicals. Chromium enhances an alloy's hardenability, creep and impact strength, and resistance to corrosion, oxidation, and wear. Ferrous alloys, mainly stainless steels, account for most of the consumption. These steels have a wide range of mechanical properties as well as being corrosion and oxidation resistant. Cast irons may contain from 0.5 % to 30 % Cr, which provides hardenability, toughness, hardness, and corrosion and wear resistance. Chromium is widely used in nonferrous alloys, including those based on nickel, iron – nickel, cobalt, aluminum, titanium, and copper. In Ni, FeNi, and Co, Cr is used for oxidation and corrosion resistance. In Al, Ti, and Cu it controls the microstructure.

Chromium chemicals are used in a variety of applications. The largest amount is consumed to manufacture pigments for use in paints and inks. Other applications include leather tanning, metal corrosion inhibition, drilling muds, textile dyes, catalysts, and wood and water treatment.

Chromite is used in the refractory industry to make bricks, mortar, and ramming and gunning mixes. Chromite enhances thermal shock and slag resistance, volume stability, and strength.

1.6. Economic Aspects

The world production of chromium fluctuated between 1973 and 1983; however, growth is expected to the end of the century. Data for worldwide production are as follows [4]:

Year	Production, 10^3 t	Year 10^3 t	Production,
1973	1999	1979	2936
1974	2207	1980	2973
1975	2540	1981	2786
1976	2669	1983	2490
1977	2883	1982	2489
1978	2820	2000	5625 *

* Probable projected demand.

2. Chromium Alloys

In the manufacture of steel, chromium is added usually in the form of ferrochrome (see Chap. 3). Pure chromium metal, produced by electrolytic or aluminothermic processes, is used for alloying nonferrous engineering materials. The most common materials are nickel-based and cobalt-based alloys, most of which are used at high temperature.

The only true chromium-based alloys that have been developed and used commercially are a few chromium – nickel alloys developed by the International Nickel Co. (INCO). These materials contain 50 – 60 % chromium; the remaining percentage is nickel, with either niobium (columbium) or titanium specified as carbon and nitrogen scavengers. These alloys, as well as materials cited in [16], [17], often referred to as *superalloys*, are used in constructing high-temperature exposed components in chemical and petrochemical industries.

Chromium-based alloys have found a unique application in power stations as supports for heat exchanger pipes. The balance of cobalt- and nickel-based high-chromium alloys are used mainly in components for gas turbine engines and for parts requiring resistance to elevated temperature, oxidation, and hot corrosion.

Chromium alloys of Ni, Fe – Ni, and Co are produced in a ratio of about 10 : 5 : 1; total annual production is ca. 7×10^4 t. By far the alloys produced in greatest quantity are the solution-hardened types, such as alloy 600 (75 % Ni – 15 % Cr – 10 % Fe) and alloy 800 (35 % Ni – 20 % Cr – balance Fe). Special purpose Ni – Cr – Mo alloys, which have generated a significant volume, include Hastelloy X and alloy 625. These alloys are used in sheet, plate, bar, wire, and tube forms for a wide variety of applications in industries, such as petrochemical, chemical processing, heat treatment, pollution control, nuclear power, and transportation.

The most widely used *wrought* nickel-based age-hardened superalloys are Waspaloy and alloys 700 and 718. Popular iron – nickel superalloys include 901 and A – 286. The only wrought cobalt-based alloy used in any volume is Haynes 188. *Investment cast superalloys* include 713 and 718 and the cobalt-based alloy X – 40. Wrought and cast superalloys are used primarily in static and rotating parts for gas turbine engines, although they are also used for other applications, including petroleum production. Because of the demanding service required of these very expensive alloys, many special purpose proprietary compositions have been developed.

Advances in *nickel-based alloys* include prealloyed powders, coating technology, rapid solidification, single-crystal technology, oxide dispersion, strengthening, and metal matrix composites. Although all of these developments are for products with relatively low commercial volume, they represent the leading edge of materials technology and have spurred a new series of unique alloys.

Producer and user specifications may allow for substitution of a special quality ferrochromium for chromium metal [18]. Chromium metal is also required in a few examples of iron-based engineering alloys in which the use of ferrochromium would introduce undesirable levels of certain elements deleterious to the physical properties of the end product, such as aircraft landing gears [19].

Chromium metal in powder form is used in the manufacture of *cermets* (→ Ceramics, Ceramic – Metal Systems), [20]. The cermets of commercial importance are as follows:

Cermet LT – 1	77 % Cr, 23 % Al_2O_3
Cermet LT – 1 B	59 % Cr, 19 % Al_2O_3, 20 % Mo, 2 % TiO_2
Cermet LT – 2	25 % Cr, 15 % Al_2O_3, 60 % W

These particular cermets have very good thermal stability and corrosion resistance. Both LT–1 and LT–1 B exhibit good creep resistance up to 1200 °C. Cermets are used for thermocouple tubes, crucibles for ovens, shuttles in the textile industry, gas tubes and rings in gas turbines, components of sulfuric acid pumps (LT–1), and for inserts in rocket nozzles (LT–2). Other applications are crucibles, pans, casting molds, casting forms, and nozzles.

Small alloying additions of chromium to *copper* between 0.3 % and 1.2 % are used to provide higher strength and, in some applications, abrasion resistance, while reducing conductivity only slightly. Copper – chromium alloys are used for electrode tips for spot welding in the automotive industry, rotating contact parts, rings, and other electrical applications [20]. Rapid solidification processing and solid-state microblending has resulted in the development of a more homogeneous microstructure in copper – chromium alloys [21].

Wrought aluminum alloys contain small amounts of chromium (0.10 – 0.3 %) in addition to other alloying elements, such as magnesium and manganese [22].

Cast aluminum alloys contain 0.05 – 0.40 % chromium [23]. In both the cast and wrought aluminum alloys, the chromium imparts increased corrosion resistance and improved physical properties.

Chromium metal from electrolytic or aluminothermic processes is used in a briquetted aluminum powder compact to provide the alloying addition to both cast and wrought aluminum products [24]. Two grades of smelted binary aluminothermic chromium – aluminum alloys (10 % chromium and 20 % chromium) are also used.

Other binary aluminothermic chromium alloys available for special alloying requirements are chromium – molybdenum (30 % Mo) and niobium – chromium (30 % Nb). Chromium – tungsten binary alloys were once used but are now redundant [25], [26].

Metallic chromium powders are used in both coated and cored welding electrodes. Small quantities of pure chromium are used for anodes in X-ray tubes and also for vacuum vaporization or sputtering.

Chromium powder, as well as ferrochromium powder, has been used in considerable quantities to produce *chromium coatings.*

The so-called pack chrome coating [26], [27] is applied to cast and wrought steel parts by immersing the article in a mixture of chromium powder; an inert material, e.g., kaolin, alumina, or magnesia; and mixtures of various salts, such as ammonium, iodide, or chloride. The packed part is then heated in an inert atmosphere at 900 – 1300 °C (heating time is dependent on part size).

Another procedure is the so-called gas chromium coating [27]. Steel parts and the chrome coating mixture are placed in a vessel at 1050 – 1250 °C. Volatile chrome compounds react with the steel components. The coating mixture consists mostly of chromium powder (both chromium metal and ferrochromium have been used [28]); inert materials (similar to those used in the pack chromium coating); and a relatively high concentration of a salt (fluoride, ammonia, or cryolite).

The gas chromium coating has been used to produce a so-called tin-free steel and to treat sheet steel on a continuous line.

Although chrome plating is used to produce a shiny as well as a hard satin finish, the source is from chromium salts rather than from aluminothermic or electrolytic chromium.

Chromium as the main alloying component has been reported in the literature [29], [30]. To date, none of these alloys is industrially significant. The cited reasons for lack of commercial application are the lack of ductility and the difficulty of processing these chromium-based alloys. Some of the alloys investigated that appear promising and the properties studied are listed in Table 3 (see next page) [29], [30].

3. Ferrochromium and Other Chromium Master Alloys

Ferrochromium is a master alloy of iron and chromium, containing 45 – 95 % Cr and various amounts of iron, carbon, and other elements. The ferrochromium alloys are classified by their carbon content and are known by their French names because basic work in this field was carried out mainly in France:

1) *High-carbon ferrochromium* (HC ferrochromium) with 4 – 10 % C, "ferrochrome carbure"
2) *Medium-carbon ferrochromium* (MC ferrochromium) with 0.5 – 4 % C, "ferrochrome affiné"
3) *Low-carbon ferrochromium* (LC ferrochromium) with 0.01 – 0.5 % C, "ferrochrome suraffiné"

The mechanical and chemical properties of steel can be improved by alloying it with ferrochromium. Chromium combined with nickel gives stainless steel excellent chemical resistance (see Chap. 1).

The first industrial use of ferrochromium in producing low-chromium alloy steels was in 1860 – 1870 in France. Previously P. Berthier (1821) and E. Fremy (1857) produced small quantities of high-carbon ferrochromium in crucibles by reducing chromite or combinations of chromium and iron oxides with charcoal. This direct reduction process was transferred to the blast furnace or cupola to produce low-chromium alloys with 7 – 8 % Cr, and later on alloys with 30 – 40 % Cr. In the United States (1869), Sweden (1886), and Russia (1875), similar processes were developed for producing high-carbon ferrochromium [26, pp. 1 – 3], [31].

The fundamental work by Moissan (1893) on using the electric arc furnace and its industrial application for the direct carbothermic production of high-carbon ferrochromium by Héroult (1899) were major improvements over the blast furnace that led to the modern large-scale production.

Table 4. Some physical properties of ferrochromium and ferrosilicochromium [32]

Alloy	Density (ϱ), g/cm^3	Melting range, °C	
		Liquidus	Solidus
Chromium metal (electrolytic)	7.2	1900	
Chromium metal (aluminothermic)	7.2	1850

Ferrochromium silicon (36 % Cr, 40 % Si)	5.3	1388	1360

∗ Charge chrome (see Table 10, and Section 3.4,)

The reduction of chromite by silicon for the production of low-carbon ferrochromium was developed by F. M. Beckett (1907) and improved by G. Jean (1909).

The aluminothermic production of low-carbon ferrochromium has proved to be too expensive and the method is seldom used now.

3.1. Physical and Chemical Properties

Low-carbon ferrochromium has a bright silvery appearance; as carbon content increases, the metal turns from gray to dark gray. The density and melting range for different grades of ferrochromium are summarized in Table 4 (see previous page) [32].

The Fe – Cr phase diagram (see Fig. 3, [33]) exhibits a continuous series of solid solutions at higher temperature and a σ-phase at lower temperature. This brittle σ-phase has a tetragonal structure ($a = 8.7995 \times 10^{-10}$ m, $c = 4.5442 \times 10^{-10}$ m).

Figure 3. Fe – Cr phase diagram [33]

Commercial ferrochromium contains mainly carbon as a constituent element because of the high affinity of chromium for the carbon used in the reduction process. The constitution and structure of the C – Cr – Fe system has been reviewed [34]. A projection of the liquidus temperatures and solid-phase equilibrium by isothermal sections from 1150 to 600 °C have been published [34].

3.2. Raw Materials

The only raw materials for the production of ferrochromium are chromite ores. The mineral chromite has a spinel structure and its formula may be written as $(Fe^{2+}, Mg)O \cdot (Cr, Al, Fe^{3+})_2O_3$ (→ Chromium Compounds). A high Cr : Fe ratio is advantageous to produce an alloy with high chromium content. Chromite ores are classified as follows [35]:

1) Ores rich in chromium: > 46 % Cr_2O_3, Cr : Fe > 2 : 1; for the production of ferrochromium
2) Ores rich in iron: 40 – 46 % Cr_2O_3, Cr : Fe < 2 : 1; for the production of charge chrome and for the chemical industry
3) Ores rich in aluminum: > 60 % ($Cr_2O_3 + Al_2O_3$), > 20 % Al_2O_3; for refractories

Metallurgical-grade chromite ores are classified as hard lumpy or friable lump types, fines, and concentrates. Concentrates are produced by mechanical upgrading of lean ores or fines [36].

In the production of high-carbon ferrochromium, which is by far the alloy in greatest demand, generally a lumpy type of chromite ore is necessary. The submerged arc smelting of high-carbon ferrochromium by direct reduction of carbon in large low-shaft electric furnaces generally requires lumpy chromite ores to allow the reaction gases to pass from the lower reaction zone to the top of the furnace, where the burden (i.e., charge) is continuously charged.

About 80 % of chromite ores in the western world are fines (< 10 mm). Therefore, efforts have been made to agglomerate these fines, by either sintering, briquetting, or pelletizing [37]. Fines of chromite ores can be used to produce low-carbon ferrochromium.

Typical analyses of some important metallurgical chromite ores are summarized in Table 5 (see next page) [38].

Table 5. Analyses of some chromite ores, metallurgical grade

Compound	Chromite ore, wt %				
	Transvaal lump [a]	Zimbabwe friable [b]	Former USSR lump [c]	Turkey lump [d]	Albania lump

[e] L.O.I. = loss on ignition.

The reducing agent for chromite is usually carbon in the form of coke (gas coke, coal, or charcoal); its contents of S and P should be low. Silicon as a reducing agent is used in the form of ferrosilicochromium or ferrosilicon to produce low-carbon ferrochromium. Fluxing agents, e.g., quartzite or alumina (corundum or bauxite) and lime, are charged with the burden for slag formation. In the carbothermic production of ferrosilicochromium, chromite and quartzite are used as the raw materials.

3.3. Production

The oxides of iron and chromium present in the chromite can be readily reduced at high temperature with carbon. Because of the tendency of chromium to form carbides, a carbon-containing alloy is always obtained. The oxides can also be reduced with silicon, aluminum, or magnesium. However, only carbothermic and silicothermic reductions are used commercially. The reducibility of chromite depends on its composition. A chromite rich in iron ($FeO \cdot Cr_2O_3$) can be reduced by carbon at lower temperature than one rich in magnesium ($MgO \cdot Cr_2O_3$) [39], [40]. Iron oxide is reduced by carbon at a lower temperature than chromium oxide.

A thermodynamic analysis of carbothermic reactions in the field of ferroalloys has been performed [41]. For the carbothermic reduction of FeO, Cr_2O_3, and SiO_2, equilibrium temperatures at different CO pressures were calculated. The values in Table 6 were found at 101.3 kPa. Carbides with higher carbon content formed initially at lower temperature react at higher temperature with Cr_2O_3 and form carbides with lower carbon content; finally, reduction of SiO_2 starts at higher temperature. Therefore, production of ferrosilicochromium alloys requires high temperature.

Table 6. Equilibrium temperatures for various carbothermic reduction reactions [41]

Condensed reactants	Condensed products	Gases	Equilibrium temperature, °C
FeO, C	Fe	CO_2, CO	670
Cr_2O_3, C	Cr_3C_2	CO	1150
Cr_2O_3, Cr_3C_2	Cr_7C_3	CO	1190
Cr_2O_3, Cr_7C_3	$Cr_{23}C_6$	CO	1530
Cr_2O_3, $Cr_{23}C_6$	Cr	CO	1810
SiO_2, C	SiC	CO	1480
SiO_2, SiC	Si	CO, Si	1710

In practice the reactions are somewhat more complicated because iron-containing chromium carbides are formed. In high-carbon ferrochromium, the double carbide $(Cr, Fe)_7C_3$ is present. In this compound, two to four Cr atoms can be substituted by iron atoms. Equilibrium temperatures have been calculated for the FeO reduction in chromite [40]:

$$FeO \cdot Cr_2O_3 + C \rightleftharpoons Fe\,(\alpha, \beta, \gamma) + Cr_2O_3 + CO \qquad t = 950\,°C$$

For the Cr_2O_3 reduction:

$$MgO \cdot Cr_2O_3 + 13/3\,C \rightleftharpoons 2/3\,Cr_3C_2 + MgO + 3\,CO \qquad t = 1200\,°C$$

Because the difference in temperature between these two reactions is slight and because iron also facilitates reduction of chromium

oxide, selective reduction of iron is difficult. In solid-state reduction studies on Transvaal chromite, the amount of iron and chromium found in the metallic state at 1000 °C was 11.0 % of the iron and 1.3 % of the chromium, and at 1200 °C was 98.3 % of the iron and 38.5 % of the chromium [38].

In the carbothermic reduction process, unreduced oxides from the chromite (MgO, Al_2O_3) and from the gangue (SiO_2 in serpentine and olivine) are collected in a slag, which generally contains 30 % SiO_2, 30 % MgO, and 30 % Al_2O_3. The remaining 10 % is composed of Cr_2O_3, CaO, MnO, and FeO [39]. Control of slag composition is important with respect to melting temperature and fluidity. The approximate melting temperature may be derived from the ternary diagram for $MgO-Al_2O_3-SiO_2$ [42].

Low-carbon ferrochromium is produced by the silicothermic reduction of chromite ore. Silicon is used in the form of ferrosilicochromium, which is produced in submerged arc furnaces (as is high-carbon ferrochromium) by carbon reduction of chromite ore and quartzite. The solubility of carbon in the FeSiCr alloy depends on the silicon content; if the silicon content is higher, the carbon content is lower. The carbon solubility at different silicon contents and temperatures is shown in Table 7 [43]. The reduction of Cr_2O_3 by Si is enhanced by addition of lime (CaO), which reduces the activity of SiO_2 in the slag. The reduction may be written as follows:

$$FeO \cdot Cr_2O_3 + 2\,Si + 4\,CaO \longrightarrow (2\,Cr + Fe) + 2\,Ca_2SiO_4$$

Special chromium master alloys like CrMo, CrW, and CrNb are produced aluminothermically by coreduction of the relevant oxides together with chromium oxide (see Section 1.4).

3.3.1. High-Carbon Ferrochromium

High-carbon ferrochromium is produced by direct reduction of chromite ores with carbon (coke, coal, or charcoal) in large, three-phase submerged arc furnaces with 10 – 50 MV · A capacity (corresponding to 15 000 – 60 000 t/a of ferrochromium production). Elkem in Sweden operates the largest known electric arc furnace with 105 MV · A capacity. This furnace is used to produce high-carbon ferrochromium and ferrosilicochromium.

Submerged arc furnaces work continuously as a low-shaft electric furnace, where the burden is charged around the self-burning Søderberg electrodes. These electrodes are deeply immersed in the burden column and discharge to the reduced liquid products, i.e., the metal and slag, on the bottom of the furnace. Metal and slag are tapped at regular intervals through tapholes near the furnace bottom; they flow into a ladle with a slag overflow leading to another ladle or to a slag pan. After the slag has been skimmed, the metal is poured into heavy, flat cast-iron molds lined with sand or into sand molds. The furnace hearth and the walls in the reaction zone are normally lined with carbon blocks or a ramming mix; in special cases, magnesite is used. The walls of the shaft are lined with fireclay or magnesite.

In older plants with relatively small submerged arc furnaces, the CO reaction gas is burned at the top of the furnace and then scrubbed. Modern submerged arc furnaces with high capacities are totally closed, and the unburned reaction gas (ca. 90 % CO) is scrubbed. Thus, the volume of the off-gas can be minimized (by a factor of 10 – 20 compared to that of the open top furnace), and the investment costs for the gas-cleaning plant are correspondingly lower. Furthermore, the combustible gas can be

Table 7. Solubility of carbon in ferrosilicochromium as a function of temperature, calculated from equations given in [43]

Silicon content ∗,	Carbon content, wt %

∗ Cr : Fe = 2.67.

used as a fuel for processes, such as calcining the limestone and drying and preheating the ore or the whole burden, or for producing energy.

The coke rate is calculated on the basis of the stoichiometric requirement of the oxides and on the amount of dissolved carbon in the alloy; allowance is made for some combustion at the top of the furnace and for reaction with moisture. The slag composition is important to produce metal of desired quality and to maintain smooth furnace operation. Therefore, the slag is analyzed from tap to tap or once per shift, and the additives are altered accordingly. In modern plants, calculation of the burden and collection of data from the furnace are computerized [44].

The silicon content in high-carbon ferrochromium is dependent on the reduction temperature. High-melting slags lead to higher silicon content in the alloy (see below; ferrochromium with 4 – 6 % C). A typical slag composition is 30 – 33 % SiO_2, 26 – 28 % Al_2O_3, 20 – 25 % MgO, 3 – 7 % CaO, and 8 – 13 % Cr_2O_3 for charge chrome containing 52 – 54 % Cr, 6 – 7 % C, and 2 – 4 % Si produced from Transvaal ore or charge chrome containing 63 – 67 % Cr, 5 – 7 % C, and 3 – 6 % Si produced from Zimbabwe ore.

The lumpiness of the ore and the coke quality are important to maintain a proper submerged arc process. Because of the high coke rate (ca. 25 %), the coke properties (size, bulk density, volatile matter, and fixed carbon) are mainly responsible for the electrical resistance of the burden.

The current/potential ratio (*I/U*) is particularly important for large furnaces to maintain a reasonable power factor [45]; as a rule, *I/U* is approximately 200. Therefore, the electric power must be supplied at high current and low potential (e.g., 50 kA at 250 V). Specially constructed leads to the electrodes are necessary to carry the secondary current in order to avoid self-induction and energy losses [46].

Because more than 80 % of chromite ores mined in the western world are finer than 10 mm, agglomeration processes have been adopted to provide a good burden porosity in the electric arc furnaces, especially in the larger ones [37]. In some ferrochromium plants, fines and lumpy ores are blended in ratios between 1 : 1 and 4 : 1. Thus, Union Carbide in Tubatse, South Africa, produces 120 000 t/a of charge chrome in three open submerged arc furnaces, each with a capacity of 30 MV · A. A blend of 80 % fines and 20 % lumpy ore is used. A submerged arc process can be maintained by using raking machines to break the crusts that are formed [47]. A Cr recovery of 75 % was achieved for the production of a charge chrome containing 52.5 % Cr, 6.4 % C, 3.5 % Si, 0.04 % S, and 0.02 % P, and a slag containing 38 % SiO_2, 25.5 % MgO, 4.5 % CaO, 32 % Al_2O_3, and 13 % Cr_2O_3. The power consumption was 4000 kW · h/t of alloy.

Middelburg Steel & Alloys in South Africa installed a briquetting plant with a capacity of 250 000 t/a. The use of briquettes improved the furnace performance and resulted in higher productivity and lower specific energy consumption. In two semiclosed submerged arc furnaces, each with a capacity of 30 MV · A, 100 000 t/a of charge chrome (53.5 % Cr, 7.4 % C, 2 – 3 % Si, 0.015 % S, and 0.015 % P) was produced with a power consumption of 3800 kW · h/t of alloy [48].

Pelletizing of chromite fines and concentrates as an agglomeration process has been adopted by Gesellschaft für Elektrometallurgie (GfE) in the Federal Republic of Germany using the Lepol (grate kiln) process [49], and by Ferrolegeringar in Trollhättan, Sweden, using the Cobo (cold bond) process [50]. These pellets can be used for the production of ferrochromium and silicochromium.

Sintered chrome ore fines were used successfully in Japan. However, briquetting is the main agglomeration method used [37].

Figure 4 (see next page) shows the new process developed by Outokumpu Oy in Finland for the production of ferrochromium from their own chromite-containing deposit near the town of Kemi [51], [52].

The chromite concentrate is pelletized, using bentonite as a binder. After sintering in a shaft furnace, the pellets are blended with fluxes and coke. This burden is then preheated in a rotary kiln at 1000 – 1100 °C and charged to a fully closed 24 MV · A submerged arc furnace producing 60 000 t/a of charge chrome (53.5 % Cr, 7 % C, and 2.5 % Si) and slag (30.2 % SiO_2, 24.9 % MgO, 6.8 % CaO, 25.9 % Al_2O_3, 6.8 % Cr, and 1.8 % Fe); Cr recovery is 84 %. The off-gas from the furnace (ca. 90 % CO) has a heat value of 3.07 kW · h/m^3 (STP) and is used as a fuel for the shaft furnace and for heating the kiln.

Figure 4. Outokumpu Oy high-carbon ferrochromium process [51], [52]

This technology results in a low specific energy consumption of 2600 – 2800 kW · h/t of charge chrome. The process has been adopted in other countries (Orissa Mining in India, Elazig in Turkey, Hellenic Ferroalloys in Greece, and Ferrochrome Philippines in the Philippines). Ferrochrome Philippines successfully began production in 1984 in a 20 MV · A furnace rated for 50 000 t/a of high-carbon ferrochromium [53].

A further improvement in specific energy consumption was achieved by the SRC process (solid-state reduction of chrome ores), developed by Showa Denko K. K. in Japan [54], [55]. This process is shown in Figure 5. The addition of carbon and flux during pelletizing resulted in a reduction of iron oxide and a partial reduction of chromium oxide during sintering in a rotary kiln at 1350 – 1450 °C. Hot charging a burden containing 60 % prereduced pellets in a closed 18 MV · A submerged arc furnace required an energy consumption of 2000 – 2100 kW · h/t of alloy for an annual production of 50 000 t high-carbon ferrochromium (57 – 60 % Cr, ca. 8 % C, and ca. 3 % Si). This process was also adopted by Johannesburg Consolidated Investment (South Africa) in a 180 000 t/a ferrochromium plant.

Figure 5. Showa Denko high-carbon ferrochromium process [54], [55]

A special ferrochromium 4 – 6 % C grade with 60 – 72 % Cr and max. 1.5 % Si was used for many years in the steel industry before inexpensive charge chrome from South Africa became more attractive. This ferrochromium is not sat-

urated with carbon. It is produced the same way as charge chrome in large submerged arc furnaces, but with a magnesite lining instead of a carbon lining. This process has been improved by using chromite ore mixes containing a definite fraction of hard and lumpy refractory ores with a high MgO content to produce a high-melting slag (e.g., 29 – 32 % SiO_2, 32 – 35 % MgO, 29 – 32 % Al_2O_3, and 3.5 – 6.0 % Cr_2O_3) [56], [57]. At a higher reduction temperature of 1500 – 1700 °C, the following refining reaction of the refractory ore takes place [40]:

$$3\,(Cr, Fe)_7C_3 + Cr_2O_3 \longrightarrow (Cr, Fe)_{23}C_6 + 3\,CO$$

Because of the low sulfur specification (< 0.05 %) in this grade, coke with low sulfur content is used as the reductant; 30 – 35 % of the sulfur in the coke is transferred to the metal. Alternatively, desulfurizing slags may be used. The ferrochromium can be poured into a highly basic fluid slag, e.g., slag from the LC-ferrochromium process. The sulfur forms CaS, which is removed in the slag.

A new process for producing ferrochromium with 5 % C and < 1 % Si from unagglomerated chromite fines in a transferred arc plasma furnace has been developed by Tetronics Research & Development [58]. Commercialization of this process has been accomplished in South Africa, where a 10.8 MV · A plasma furnace has been built [59].

3.3.2. Medium-Carbon Ferrochromium

Medium-carbon ferrochromium with 0.5 – 4 % C can be produced by refining high-carbon ferrochromium or by silicothermic reduction of chromite ores. Batch refining of high-carbon ferrochromium with refractory chromite ores in an electric arc furnace is no longer used because of the high power consumption of 8000 – 9000 kW · h/t of ferrochromium [46].

Decarburization of high-carbon ferrochromium in an oxygen-blown converter is more economical, especially on a large scale. In the United States and Japan, a top-blowing process with oxygen using water-cooled lances to the metal surface was used. In the Federal Republic of Germany, a bottom-blowing process (OBM = oxygen bottom Maxhütte or Q-BOP) was introduced in the 1970s [60]. This process is characterized by oxygen injection from the bottom into the metal bath with the oxygen jet, resulting in a high decarburization rate of ca 0.3 % C/min. Because of the high bath temperature (1800 – 1850 °C), mainly the carbon is oxidized. Chromium recovery is high; for example, recovery of product with 0.8 – 1 % C is 85 %, and it is improved to 90 – 93 % by adding silicochromium and lime. A typical sequence for a blow is shown in Figure 6 [61].

Figure 6. Sequence of an OBM-oxygen blow of high-carbon ferrochromium [61]

Because demand for medium-carbon ferrochromium is small compared to demand for the high-carbon material, the decarburization processes are rarely used. However, reduction of chromite ores with silicon in the form of silicochromium is used and is an economical production method for medium-carbon ferrochromium because the low-carbon grade can be produced as well. To make ferrochromium with 1 – 2 % C, a silicochromium alloy with a Si content of 25 – 30 % can be used (see Table 7, p. 52). The

power consumption, including the energy for silicochromium, amounts to 5000 – 6000 kW · h/t of ferrochromium (see Section 3.3.3).

3.3.3. Low-Carbon Ferrochromium

Low-carbon ferrochromium is produced mainly by silicothermic reduction of chromite ores. This process dates back to the Swedish *three-step process* introduced in 1920 by A. B. Ferrolegeringar in Trollhättan [46].

In step one, chromite ore was totally reduced with carbon in an electric arc furnace to an intermediate ferrochromium (Halbprodukt) with 60 – 65 % Cr, 5 – 6 % C, and 5 – 7 % Si, and a discard slag. In step two, this intermediate ferrochromium was smelted with quartzite and coke in a slagless process to produce silicochromium (40 – 45 % Si, ca. 40 % Cr, and < 0.5 % C). Finally, this silicochromium was used as a reductant in the third step; the crushed alloy was thrown onto the surface of a chrome ore – lime melt in an arc furnace. The tapped ferrochromium contained ca. 70 % Cr, ca. 1 % Si, and 0.03 – 0.05 % C. The slag, which contained 20 – 25 % Cr_2O_3, was returned to the first step to improve Cr recovery.

This Swedish process was modified, especially when the direct silicochromium production by carbothermic coreduction of chromite ore and quartzite in large submerged arc furnaces in one step proved more economical than the slagless process. Furthermore, the silicothermic conversion was improved by adding more lime to form a highly basic slag (CaO/SiO_2 ratio of ca. 2). Thus, ferrochromium with < 1.5 % Si was produced with a lean slag (ca. 5 % Cr_2O_3) in one step. Residual elements, i.e., S and N, were low (< 0.01 % and < 0.02 %, respectively). The power consumption was 3000 – 3500 kW · h/t of ferrochromium for the silicothermic process (arc furnaces with 2 – 10 MV · A capacity) and, including the power consumption for the silicochromium production, was 8000 – 9000 kW · h/t ferrochromium.

The most important process for the production of LC ferrochromium is the Perrin process, developed in 1937 by the Sociétié Ugine in France [62]. This process combines the direct reduction of silicochromium in a submerged arc furnace with a countercurrent silicothermic reduction of a chrome ore – lime melt (produced in an arc furnace) in a reaction ladle.

Production of Silicochromium. Silicochromium is not only used as a reductant in the production of LC ferrochromium, but also as an alloying and deoxidizing agent in the steel industry.

Silicochromium is made in large three-phase submerged arc furnaces of 10 – 36 MV · A capacity. These furnaces are of the same type as those used to produce HC ferrochromium. The lower reaction zone is lined with carbon and the upper side walls of the furnace shaft are lined with fireclay bricks. Maintaining the Søderberg electrodes deep in the burden column (30 – 50 cm above the hearth) is important to reduce the SiO_2 to Si. Therefore, coke with low electric conductivity and low bulk density (< 400 kg/m^3) is used (e.g., gas coke).

The electrical conditions in silicochromium furnaces are somewhat different from those in furnaces used to produce HC ferrochromium; e.g., the current/potential ratio is higher (I/U = ca. 500) [46]. The volume of $CO_{(g)}$ from silicochromium production is much higher than from HC ferrochromium production. Therefore, a porous burden is essential. To scrub the huge volumes of $CO_{(g)}$ produced, modern silicochromium furnaces are closed systems, and the unburned gas is used as a fuel.

To produce an alloy composed of 45 % Si, 40 % Cr, and 0.02 % C, a burden containing 100 parts of a refractory chromite (high Cr/Fe ratio of ca. 3 and a MgO/Al_2O_3 ratio of 1.2 – 1.4), 110 parts of quartzite, and 65 parts of coke (85 % fixed C) is continuously charged to the submerged arc furnace. Metal and slag are tapped every few hours. The slag contains 48 – 50 % SiO_2, 25 – 27 % MgO, 19 – 21 % Al_2O_3, and 1 – 3 % Cr_2O_3. The Cr recovery is 93 – 95 %, and the power consumption is 7500 – 8500 kW · h/t of alloy (45 % Si). The power consumption is primarily dependent on the Si content of the alloy. For a silicochromium with 40 % Si and 45 % Cr, the power consumption is 6500 – 7500 kW · h/t.

Production of LC Ferrochromium by the Perrin Process. Single-stage silicochromium production is one portion of the Perrin process. This process requires two furnaces: a submerged

arc furnace to produce silicochromium and an open-top electric arc furnace to melt a chromite ore – lime slag. A flow sheet of the entire process is shown in Figure 7.

Figure 7. Low-carbon ferrochromium production by the Perrin process [62] (according to [39])

The silicochromium and slag from the submerged arc furnace are tapped to a lined segregating ladle and are allowed to settle for 1 – 2 h. Dissolved SiC floats to the top. The separated alloy (40 – 45 % Si, 45 – 40 % Cr, and 0.05 – 0.02 % C) is removed through a taphole at the bottom of the ladle. The alloy is reacted with an intermediate liquid slag (8 – 10 % Cr_2O_3) in a second basic-lined reaction ladle to produce an intermediate alloy and a discard slag. The intermediate alloy (20 – 25 % Si, 60 – 55 % Cr, and 0.05 – 0.03 % C) is allowed to solidify and is separated from the slag (< 1 % Cr_2O_3). Because of its high basicity, the slag disintegrates to powder (falling slag).

The rich slag (chrome ore – lime melt with 25 – 27 % Cr_2O_3, 7 – 8 % FeO, 2 – 3 % SiO_2, and 45 – 48 % CaO) is tapped from the open-top electric arc furnace in weighed amounts to another basic-lined reaction ladle. Crushed intermediate alloy from the first reaction ladle is added to form the desired LC ferrochromium (ca. 70 % Cr, < 1.5 % Si, and 0.02 – 0.05 % C) and an intermediate slag (8 – 10 % Cr_2O_3). This slag is reacted with silicochromium to lower the Cr_2O_3 content to < 1 %.

Production of 1 t of silicochromium by this process typically requires 1450 kg of chrome ore, 1500 kg of quartzite, 870 kg of coke, 32 – 35 kg of electrodes, and 7700 kW · h power [39]. Production of 1 t of ferrochromium requires 1440 kg of chrome ore, 1250 kg of lime, 660 kg of silicochromium (45 % Si and 40 % Cr), 22 kg of electrodes, and 3200 kW · h power.

Therefore, the total energy consumed to produce 1 t of LC ferrochromium, including silicochromium production, is 8200 kW · h. The overall recovery of Cr by the Perrin process is 90 – 92 %.

Low-carbon ferrochromium is tough and difficult to break. Therefore, it is poured into flat molds, sometimes filled with liquid slag to protect the mold. Quenching the hot alloy in water facilitates breaking it into small lumps, which is performed with heavy pneumatic hammers.

Many variations of the Perrin process have been developed. For example, chrome ore or lime have been added to the exothermic reactions, which occur in the two reaction ladles (Fig. 7), to "dampen" the reaction and to save energy. Another variation is the selective reduction of FeO, producing an iron-rich alloy; the remaining slag, high in Cr_2O_3, is reacted with silicochromium high in Si, to give LC ferrochromium (80 – 90 % Cr). By selectively reducing FeO, CoO is also reduced in the iron-rich alloy and a Co-free ferrochromium can be produced. This is used to produce alloyed steels for atomic energy plants.

Production of LC Ferrochromium by the Simplex Process. From 1943 to 1953 Union Carbide developed a new production process for LC ferrochromium, the so-called Simplex process, in which finely ground HC ferrochromium was decarburized in the solid state with oxidized ferrochromium by vacuum annealing [63–65].

The plant in Marietta, Ohio, went into production in 1953 and is now managed by Elkem Metals Co., Pittsburgh, Pennsylvania. The flow sheet of the process is shown in Figure 8.

Figure 8. Production of low-carbon ferrochromium by the Simplex process [64]

High-carbon ferrochromium is crushed, pulverized in ball mills, and then oxidized in suspension in a vertical gas- or oil-fired shaft furnace [66]. The proper stoichiometric C/O ratio for decarburizing is attained by mixing the oxidized material with HC ferrochromium powder according to the following reactions:

$$3\,Cr_7C_3 + Cr_2O_3 \longrightarrow Cr_{23}C_6 + 3\,CO$$
$$1/2\,Cr_{23}C_6 + Cr_2O_3 \longrightarrow 27/2\,Cr + 3\,CO$$

The mixture is either formed into briquettes or loosely packed in corrugated pasteboard boxes, placed on a refractory topped bogie hearth (33.5 m × 3.35 m), and rolled into the vacuum chamber, which is a horizontal steel cylinder (43 m in length × 4.6 m in diameter). The graphite resistance heating elements are suspended above the charge from the refractory-lined roof. The vacuum (0.01 – 0.4 kPa) is generated by multistage steam ejectors. The process requires a special heating program up to 1370 °C, which follows the progress of decarburization. When the decarburization of the charge is complete, the power is shut off and the furnace is cooled by flooding with argon.

A complete reaction cycle requires 4 – 5 d; ca. 100 t of material is produced. A typical analysis of LC ferrochromium from the Simplex process is ca. 70 % Cr, ca. 1 % Si, and 0.008 – 0.010 % C. Oxygen is higher (ca. 1 %) than in LC ferrochromium from the Perrin process (ca. 0.2 %).

3.3.4. Nitrogen-Containing Low-Carbon Ferrochromium

Chromium has a high affinity for nitrogen and forms the nitrides Cr_2N and CrN (→ Nitrides). Low-carbon ferrochromium can form nitrides either in the solid or in the liquid state. These alloys with up to 10 wt % N are used in steel containing nitrogen as well as chromium [32]. The Simplex process is convenient for forming nitrides in LC ferrochromium in the solid state. During the cooling cycle, nitrogen is added to the vacuum vessel and the optimum temperature range of 1200 – 800 °C is held over a longer period to produce an alloy with 7 – 10 % N.

Silicothermically produced LC ferrochromium can form nitrides when pulverized and heated in boxes in a continuous annealing furnace at 1000 °C under nitrogen [67]. The sintered product (ϱ 5 – 6 g/cm^3) contains 5 – 10 % N as Cr_2N.

On the other hand, LC ferrochromium can form nitrides in the liquid state with nitrogen gas in a melting furnace, e.g., an induction furnace [68]. The tapped alloy contains 2 – 4 % N and is very homogeneous (ϱ 7.0 g/cm^3) [69].

3.3.5. Other Chromium Master Alloys

Chromium master alloys other than ferrochromium are produced in much smaller amounts. They are used mainly to produce heat-resistant alloys, based on nickel or cobalt (superalloys), and abrasion-resistant materials, and are used to alloy small amounts of chromium to copper or aluminum (see Chap. 2).

Nickel – chromium master alloys containing 50 – 80 % chromium may be made by aluminothermic processes or by melting chromium metal and nickel in induction-heated furnaces. The aluminothermic process must be performed in water-cooled molds in an inert atmosphere because of the high quality required of these master alloys [70]. For direct melting of chromium metal and nickel, a vacuum induction furnace or an inert gas atmosphere is also preferred; refining occurs simultaneously during melting [71].

Binary chromium master alloys, such as *chromium – molybdenum* (with 30 % Mo) or *chromium – niobium* (with 30 – 80 % Nb) [72], [73], are made by aluminothermic reduction of the corresponding oxides. Master alloys containing more than two metals, e.g., *cobalt – chromium – tungsten* (ca. 43 wt % Co, ca. 37 wt % Cr, ca. 16 wt % W, ca. 3 wt % C), or *cobalt – chromium – molybdenum* (26 – 30 wt % Cr, 4 – 5 wt % Mo, rest Co) [73], are made by direct melting of the metals in an inert atmosphere or in vacuum induction furnaces. *Copper – chromium* master alloys containing up to 10 wt % Cr, e.g., V – CuCr 10 [74], are made by directly alloying chromium with an oxygen-free copper melt; the resulting alloy is quickly cast into flat pigs. The same method is used for the production of *aluminum – chromium* master alloys with 5, 10, or 20 wt % Cr by alloying comminuted chromium metal with a superheated aluminum melt. The master alloy containing 5 – 6 % Al is standard in the Federal Republic of Germany, i.e., V – AlCr 5 [75]. Another aluminum – chromium master alloy containing ca. 50 wt % Cr and 50 wt % Al is made for special purposes [73].

3.4. Quality Specifications, Storage and Transportation, and Trade Names

International standards of specifications and conditions of delivery for ferrochromium and ferrosilicochromium are given in ISO 5448 [76] and ISO 5449 [77], respectively. The following specifications are contained in tables in reference [76]:

1) Chromium content of ferrochromium alloys ranges from 45 to 95 % [76, Table 1]; e.g., the designation is FeCr 50 for 45 – 55 % Cr content.
2) Composition of HC ferrochromiums with normal phosphorus [76, Table 2] and with low phosphorus content [76, Table 3]; e.g., FeCr 50 C 50 (45 – 55 % Cr, 4 – 6 % C, max. 1.5 % Si, max. 0.050 % P, and max. 0.10 % S); or FeCr 60 C 50 Si 2 LP (55 – 65 % Cr, 4 – 6 % C, 1.5 – 3 % Si, and max. 0.03 % P). HC ferrochromium is standardized to 10 % C. Ferrochromium with low sulfur content is designated LS (low sulfur, i.e., max. 0.05 %).
3) Analysis of MC ferrochromiums with normal phosphorus [76, Table 4] and with low phosphorus [76, Table 5]; carbon content ranges from 0.5 – 1.0 %, 1.0 – 2.0 %, up to 2.0 – 4.0 %, e.g., FeCr 70 C 20 (65 – 75 % Cr, 1.0 – 2.0 % C, max. 1.5 % Si, max. 0.050 % P, and max. 0.050 % S); or FeCr 60 C 10 LP (55 – 65 % Cr, 0.5 – 1.0 % C, max. 1.5 % Si, max. 0.03 % P, and max. 0.050 % S).
4) Standard chemical composition of LC ferrochromium for normal [76, Table 6] and for low [76, Table 7] phosphorus alloys; carbon content ranges from less than 0.015 %, 0.015 – 0.030 %, up to 0.25 – 0.50 %; e.g., FeCr 60 C 05 (55 – 65 % Cr, 0.030 – 0.050 % C, max. 1.5 % Si, max. 0.050 % P, max. 0.030 % S, and max. 0.15 % N) or FeCr 70 C 03 LP (65 – 75 % Cr, 0.015 – 0.030 % C, max. 1.5 % Si, max. 0.030 % P, max. 0.030 % S, and max. 0.15 % N).
5) LC ferrochromium with high chromium content (75 – 95 %) [76, Table 8]; e.g., FeCr 90 C 03 (85 – 95 % Cr, 0.015 – 0.030 % C, max. 1.5 % Si, max. 0.020 % P, max. 0.030 % S, max. 0.02 % Co, and max. 0.20 % N).
6) Nitrogenated LC ferrochromiums [76, Table 9]; the three given are smelted FeCr... C1 N3, sintered FeCr... C1 N7, and sintered

FeCr... C1 N7 Si. The Cr contents given in [76, Table 1] are valid for these alloys. The nitrogen contents are 2 – 4 % in the smelted qualities and 4 – 10 % in the sintered qualities.

7) Particle size ranges for ferrochromium deliveries [76, Table 9]; there are seven classes from 100 – 315 mm (Class 1) to $\leqq$ 3.15 mm (Class 7).

ISO Standard 5448 [76] also covers testing (sampling and chemical analysis) as well as storage and transportation according to international regulations. ISO Standard 5449 [77] for ferrosilicochromium specifications and conditions of delivery recognizes 12 different compositions with increasing Si content, ranging from FeCrSi 15 (min. 55.0 % Cr, 10.0 – 18.0 % Si, max. 6.0 % C, max. 0.050 % P, and max. 0.030 % S) up to FeCrSi 50 (min. 20.0 % Cr, 45 – 60 % Si, max. 0.1 % C, max. 0.030 % P, and max. 0.030 % S). Low-carbon and low-phosphorus grades are FeCrSi 50 LC (max. 0.05 % C) and FeCrSi 48 LP (min. 35.0 % Cr, 42 – 55 % Si, max. 0.05 % C, max. 0.020 % P, and max. 0.010 % S). The particle size of ferrosilicochromium deliveries is specified in seven classes as for ferrochromium. Ferrochromium and ferrosilicochromium are shipped in bulk or packaged in containers or steel drums.

In the United States, standards for ferrochromium and ferrosilicochromium are specified in ASTM A 101 – 73 [78] and ASTM A 482 – 76 [79]. Also recommended are methods for sampling (ASTM – E32) and chemical analyses (ASTM –E31). Comparisons between the standards in the Federal Republic of Germany for ferrochromium and ferrosilicochromium in DIN 17 565 [80] and the ISO standards are given in Tables 8 and 9 [81].

Internationally approved methods for sampling [82] and analytical determination of chromium in ferrochromium and ferrosilicochromium [83] and of silicon in ferrosilicochromium [84] are available as a draft.

[a] Alloy has no definite specification.
[b] Gesellschaft für Elektrometallurgie/Elektrowerk Weisweiler.
[c] Aktiebolaget Ferrolegeringar/Trollhätteverken.

Table 10 contains trade names and the relevant analyses of special and nonstandardized ferrochromium and ferrosilicochromium alloys. Charge chrome is a relatively cheap high-carbon ferrochromium with no definite specification (see Section 3.3.1). It can be added to a basic oxygen-blown stainless steel charge [39]. Extra-high-carbon (EHC) ferrochromium is supplied as a powder for abrasive surface-welding purposes. Simplex ferrochromium is a low-carbon ferrochromium produced by the Simplex process (see Section 3.3.3). Low-carbon and -nitrogen (LCN) and low-carbon, -nitrogen, and -silicon (LCNSi) ferrochromium are trade names for special grades used to manufacture corrosion- and heat-resistant steel. A low-carbon ferrochromium reactor grade is used to make corrosion- and heat-resistant steel for nuclear equipment. Cromax is a low-carbon, high-chromium ferrochromium used to produce heat-, corrosion-, and wear-resistant special steel. The high-chromium alloys can partly replace chromium metal in superalloys. Silicochrom 40 is mainly used for deoxidizing steel and for Cr_2O_3 reduction in slags; silicochrom 60 for alloying corrosion- and heat-resistant steel.

3.5. Uses

Ferrochromium is used principally as a master alloy to produce Cr-containing steel and cast iron [32]. Chromium alloyed in steel imparts oxidation and corrosion resistance because of the formation of a thin, continuous, impervious chromium oxide film on the steel surface.

Most ferrochromium is used to manufacture *stainless steel.* Martensitic grades with ca. 13 % Cr are used for applications such as knives, whereas ferritic grades with 18 – 22 % Cr are used as deep-drawing sheets. Austenitic CrNi steels exhibit especially good corrosion (acid) resistance and are used for equipment in the chemical industry as well as for food-processing machinery. The most widely known type is AISI 302, which contains 18 % Cr and 8 % Ni. A small amount of molybdenum further improves the acid resistance. Heat-resistant steel (24 – 26 % Cr and 19 – 21 % Ni) is used in power stations for steam boilers and heat exchangers; superalloys based on nickel or cobalt (ca. 30 % Cr) are used for gas turbine parts.

Chromium addition to steel also improves its mechanical properties (ability to harden,

wear resistance, and retention of strength at elevated temperature). Steel with 0.5 – 2.0 % Cr is widely used in the automotive industry as case-hardening steel ($\leqq$ 0.2 % C and 1.4 – 2.1 % Ni) and heat-treatable steel (0.2 – 0.5 % C, 0.9 – 2.1 % Ni, and 0.15 – 0.35 % Mo). Abrasion-resistant steel for ball bearings is alloyed with 0.5 – 1.6 % Cr (ca. 1 % C and 0.2 % Mo). Permanent magnetic steel contains 1 – 3 % Cr (1.0 – 1.3 % C). In tool steel for cold and hot working and high-speed steel, up to 14 % Cr is alloyed as carbide (in addition to carbides of W, Mo, and V). Stellites (35 – 70 % Co, 25 – 33 % Cr, 10 – 25 % W, and 2 – 4 % C) are highly resistant to abrasion and are used for cutting tools.

Addition of up to 30 % chromium to cast iron improves hardness and heat resistance. Powdered ferrochromium (mainly the high-carbon grade) is used for chromizing the surface of steel or cast iron parts (pack-chromizing or case-chromizing, → Metals, Surface Treatment). A high-carbon ferrochromium with extra-high-carbon content is used in powdered form for abrasive surface welding (see Table 10, EHC Ferrochromium).

3.6. Economic Aspects

Ferrochromium is mainly consumed in highly industrialized countries producing a major amount of high-grade (stainless) steel, e.g., the United States, Europe, and Japan. However, production is shifting from these consuming countries to those with large ore resources; 93 % of the known potential chromite reserves of the world are in Africa, mainly in the Republic of South Africa, and ca. 3 % in the former States of USSR and Albania [85] (see Table 1). This shift is a consequence of modern oxygen-blowing processes in combination with argon and vacuum treatment, i.e., argon – oxygen decarburization (AOD) and vacuum – oxygen decarburization (VOD), for the production of stainless steel. These processes allow the use of cheap HC ferrochromium (charge chrome) instead of LC grades. Formerly only LC ferrochromium could be used. Because power consumption for production of HC ferrochromium is only about half that of the LC grade, the availability of cheap hydroelectric power in Scandinavia is no longer as advantageous. The change in ferrochromium consumption from LC to HC grades first took place in the United States and later, in the 1970s, in Europe [86].

In 1984, world production of marketable, i.e., lumpy, ore and concentrates was 9.2×10^6 t, 11 % of which was produced in Western Europe, Finland, Turkey, Greece, and Cyprus, 37 % in Eastern Europe (USSR and Albania), 4 % in Latin America (Brazil and Cuba), 9 % in Asia (Philippines, India, Iran, Vietnam, Japan, and Pakistan), and 38 % in Africa (South Africa, Zimbabwe, Madagascar and Sudan) [87]. In 1984, the world production of chromite ore and concentrates was 9.9×10^6 t, 72 % of which was consumed for metallurgical, 12 % for refractory, and 17 % for chemical purposes.

The metallurgical industry was the main user of chromium and consumed the following amounts in 1980 (based on United States statistics) [88]: 72 % for wrought stainless and heat-resistant steels, 13 % for wrought alloy steel, 3 % for tool steel, 7 % for cast iron and cast steel, and 5 % for other uses. In 1984, the total consumption of primary chromium units (from ferrochromium) in the United States was 195 380 t of which 79 % was for the production of stainless and heat-resisting steels, i.e., 96 kg of chromium units per ton of stainless and heat-resisting steels produced [89]. The ferrochromium consumption in the Federal Republic of Germany was 263 300 t in 1985. The change in consumption of LC to HC ferrochromium over the last 25 years is evident from Table 11 (see next page).

In 1981, consumption of ferrochromium in the western world was estimated to be $(1.32 - 1.36) \times 10^6$ t; ca. 0.5×10^6 t of this was consumed in the European Economic Community (EEC). In 1982, consumption fell drastically because of the recession in the steel industry. Consumption in the western world has since increased to ca. 2×10^6 t [90]. In 1981, the production capacity for ferrochromium plants in the western world was 3.1×10^6 t [86].

Prices of ferrochromium and ferrosilicochromium are reported weekly in *Metal Bulletin* (London). *Erzmetall* (published monthly) reports prices twice a year for raw materials and for ferrochromium. *American Metal Market* is a daily publication that also gives chromium ore and alloy prices.

Table 11. Ferrochromium consumption in the Federal Republic of Germany

	Consumption, t/a					
	1960	1965	1970	1973	1983	1985
LC ferrochromium	43 450	34 650	44 500	33 550	13 000	14 350
MC ferrochromium	20 300	24 400	16 700	18 400	7 500	11 600
HC ferrochromium	7 500	17 550	70 600	113 150	210 000	237 350
Total	71 250	76 600	131 800	165 100	220 500	263 300

Because the United States does not possess chromite deposits, most of the ferrochromium consumed is imported, mainly from Africa [91].

3.7. Environmental Protection; Toxicology and Occupational Health

Considerable attention must be paid to environmental protection during ferrochromium production. Dust evolution from ores and raw materials must be controlled during transportation and storage, and also during preparatory processes.

The off-gas from the electric arc furnaces is cleaned by using devices, such as bag filters, scrubbers, and electrostatic precipitators [46]. Bag filters are mainly used in preparatory processes, e.g., grinding, drying, briquetting [48], and pelletizing [49], and in open or semiclosed submerged arc furnaces [47], [48]. Scrubbers (Venturi and disintegrators) are preferred for cleaning unburned CO gas from closed submerged arc furnaces [51]. Effluent water from the scrubber is treated to meet wastewater regulations. Electrostatic precipitators (Cottrell filters) are also used for cleaning the off-gas from submerged arc furnaces for HC ferrochromium [92] and ferrosilicochromium [93] production. Gas from the chrome ore – lime melting furnace and from the ladle reactions during the Perrin process are cleaned with bag filters [94]. The dust content can be lowered from 150 to 20 mg/m^3 and the emission of Cr(VI) to < 1 mg/m^3 by optimizing the working conditions. Chromium(VI) is mainly responsible for the toxicity of chromium and its compounds (→ Chromium Compounds). Chromic acid, CrO_3, is carcinogenic. The Federal Republic of Germany has enacted an emission protection law and a technical guidance for clean air (TA-Luft) [95]. The TA-Luft restricts the mass of carcinogenic substances, i.e., Cr(VI) compounds (specified as Cr), in respirative form to 1 mg/m^3 (Class II). The total dust concentration in emissions is limited to 20 mg/m^3, and other inorganic materials in dust form, i.e., chromium and its compounds (Class III), to 5 mg/m^3. The maximum allowable concentration (MAK) of CrO_3 (measured as CrO_3) in the air at the workplace is 0.1 mg/m^3 [96].

In the United States the Clean Air Act Amendments, enacted in 1970, mandated the states set standards to limit air pollution. In pursuing this amendment, the U.S. Environmental Protection Agency (EPA) in a joint effort with the Ferroalloys Association studied dust emissions from alloy plants to establish ambient air quality standards [97], [98]. The states enacted process weight regulations and applied them to ferroalloy furnaces. The EPA published their studies "Engineering and Cost Study of the Ferroalloy Industry" and proposed New Source Performance Standards (NSPS) for new furnaces. A comparison of the state regulations and the NSPS (promulgated October, 1974) limitations for HC ferrochromium, charge chrome, and ferrosilicochromium for a 30-MW furnace are shown in Table 12 (see next page) [98].

Regulations on water pollution control (the federal act was passed in 1972) were also proposed by the Ferroalloys Association Environmental Committee and EPA [98]. Finally, the disposal of solid waste (slags, dusts, etc.) is also subject to regulations.

The TLV – TWA (1985 – 1986), which have been adopted, are as follows [99]: 0.5 mg/m^3 for chromium metal and chromium(II) and chromium(III) compounds, and 0.05 mg/m^3 for chromite ore processing (chromate) as Cr and chromium(VI) compounds as Cr. Chromite ore processing and certain water-insoluble Cr(VI)

Table 12. Comparison of NSPS limitations and state regulations for ferrochromium dust emissions [98]

Material	NSPS limitation,		State regulation, kg/h	
	kg/(mw · h)	kg/h	Most stringent	Least stringent
HC ferrochromium	0.23	6.94	13.00	17.55
Charge chrome	0.23	6.94	13.00	17.55
Ferrosilicochromium	0.23	6.94	8.29	10.80

compounds are listed in Appendix A1a as human carcinogens.

1. Introduction

Historical. Chrome iron ore (chromite) was discovered in 1798. A few decades later this ore was being subjected to oxidative roasting in the presence of soda and lime in manually operated furnaces to produce water-soluble sodium dichromate. This was processed further to yield yellow, red, and green chromium pigments which were used, among other things, for dyeing wallpaper; they replaced the toxic arsenic dyes that had been used until then. Chromium salts soon found their way into the textile industry as mordants for the dyeing of wool.

The importance of dichromates increased considerably in the period following 1870 when the rising coal tar dye industry needed large quantities for the oxidation of chemical intermediates. With the advent of the 20th century, chrome tanning was introduced in leather factories and in many areas replaced vegetable tanning.

The manufacture of chromium compounds received a further boost after 1930, when metallic chromium was successfully precipitated from chromic acid solutions by special additives. Since then this possibility has been used extensively in electroplating for bright and hard chromium plating.

Chromium compounds are used in numerous fields. In addition to the applications mentioned, chromates have long been used in printing as an aid in photomechanical reproduction. For some time, chromium dioxide has been a component

of magnetic tapes for information storage. Table 1 lists important applications of chromium chemicals.

Table 1. Uses of chromium compounds

Branch of industry	Product	Use
Building industry	chromium(III) oxide	pigment for coloring building materials
Chemical industry	dichromates, chromium(VI) oxide	oxidation of organic compounds, bleaching of montan waxes, manufacture of chromium complex dyes
	chromium(III) oxide	catalysts
Printing industry	dichromates	photomechanical reproduction processes
	chromium(VI) oxide	chromium plating of printing cylinders
Petroleum industry	chromates(VI)	corrosion protection
Paints and lacquers	chromates, chromium(III) oxide	pigments
Refractory industry	chromium(III) oxide	additive for increasing slag resistance
Electro-plating	chromium(VI) oxide	bright and hard chromium plating
Wood industry	chromates, chromium(VI) oxide	in mixtures of salts for protecting wood against fungi and insects
Leather industry	basic chromium(III) sulfates	tanning of smoothed skins
Metal industry	chromium boride, chromium carbide	flame sprays
	chromium(III) oxide	polishing agents
Metallurgy	chromium(III) oxide	aluminothermic extraction of pure chromium metal
Textile industry	dichromates	dyeing with chrome dyes
	basic chromium(III) acetates and chromium(III) fluorides	mordanting of textiles
Recording industry	chromium(VI) oxide	magnetic information storage
Pyrotechnics industry	dichromates	additive to igniting mixtures

2. Chromium Ores [4–16]

The distribution of chromium in terrestrial rocks is closely linked to magmatic intrusions and their crystallization. The average content in the ten-mile crust of the earth is 100 ppm of chromium [10]. Table 2 contains a worldwide estimate of chromium ore resources.

The most important applications of chromium ores are in the manufacture of stainless steel, grey cast iron, iron-free high-temperature alloys, and chromium plating for surface protection. In the nonmetallic mineral industry, chromite is processed in conjunction with magnesite (sintered magnesia, calcined magnesia) and binders (clay, lime, gypsum, bauxite, corundum). The products are intended to have good resistance to pressure, fire, and temperature change, as well as good insulating properties between basic and acidic masonry. The chemical industry uses chromium ores in the production of chromium compounds (Chaps. 34567). Table 3 shows quality requirements of chromium ores for different areas of application.

Minerals. Of the many minerals that contain chromium only the chromium spinels are of economic importance. The formula for the series of isomorphous mixtures of chromium spinels that form geological deposits is

$$(Fe^{II}, Mg)O \cdot (Cr, Al, Fe^{III})_2O_3$$

The proportion of Cr_2O_3 in the chromium spinels varies widely, causing the Cr : Fe ratio (also known as the Cr – Fe factor) to vary as well; this can have a profound effect on the evaluation of a deposit. In an ideal chromium spinel ($FeO \cdot Cr_2O_3$; 67.8 % Cr_2O_3, 32.2 % FeO) the chromium : iron ratio is 2. As a result of the isomorphous inclusion of MgO, the Cr : Fe ratio may rise to between 2.5 and 5. Figure 1 shows the region of isomorphism with varying composition of the spinels. Natural chromium spinels usually contain 33 – 55 % Cr_2O_3, 0 – 30 % Fe_2O_3, 0 –30 % Al_2O_3, 6 – 18 % FeO, and 10 – 32 % MgO. Table 4 lists some physical properties of chromium spinels.

Figure 1. Ternary spinel system showing main isomorphous region

Chromium also occurs in all groups of silicates where chromium replaces Al^{3+}, Fe^{3+}, and Mg^{2+}. Sulfidic chromium ores do not occur on earth. Chromates and chromium iodates

are described, which originate from the weathering zone of sulfidic lead deposits (e.g., crocoite, $PbCrO_4$).

Table 4. Physical properties of chromium spinels

Properties	Notes
Specific density: 3.8–4.8	increases as Fe and Cr contents increase
Hardness (Mohs): 4.5–8	increases with increase in the ferrochromite component, very high for Al spinels
Melting point: 1545–1730 °C	inclusion of Mg raises melting point, inclusion of Fe^{2+} reduces it
Color: dark brown to black	reddish with high Cr_2O_3 content
Streak on porcelain plate; hammer striking mark: brown	important feature for differentiating from serpentine

2.1. Ore Deposits

Chromium ore deposits can be divided into two genetically different types:

1) Seam-like deposits, also called stratiform or anorogenic deposits. Main representatives are Bushveld, Great Dyke, and Stillwater.
2) Deposits which are shaped like sacks or tubes; they are called podiform or orogenic deposits. Main representatives are Selukwe, Guleman, and Tiébaghi.

Various intermediate types such as adjacent "seam" pockets, striated chromite slabs, mottled ores, and vein-like deposits also occur. "Placer" deposits, i.e., enrichment due to chromite lumps

and grains on or near primary deposits, are now achieving economic importance.

The seam-like deposits reveal layers or strata of chromite enrichment, with thicknesses ranging from centimeters to decimeters; the layers are regularly interlaminated with banded series of olivine-rich or pyroxene-rich rocks. The Main Seam of the Western Bushveld is, for example, 1.10 – 1.30 m thick and can be traced for over 65 km without any significant change in the mineral composition or thickness.

The demarcation between the chromite enrichment and the underlying bed is usually razor-sharp; in the direction of the overlying layer, disintegration into layers or mottled ores as a result of increased silicate content is observed.

The chromite bodies that are sack-like to tube-like in appearance are usually aligned with the direction of the magmatic stratification, i.e., the lowest sections are massive chromite ores; in the direction of the overlying layer, these merge into striated slabs or mottled ores.

The internal texture of the chromite ore bodies varies widely. The closest chromite crystal packing results in the formation of massive ores containing 75 – 85 vol% of chromite. Sphere or leopard ores, which consist of round chromite crystal aggregates 0.5 – 2 cm in diameter in a silicate matrix (olivine, pyroxene, serpentine), are also characteristic. Banded ores are closely related to the massive ores, but they are frequently richer in silicate and then form a link with the mottled ores (chromite single crystals in silicate matrix).

During transformation (serpentinization), the silicate content within the chromite ore bodies has resulted in the formation of friable and pulverizable masses (friable ore) which are encountered not only near the surface but also at depths of several hundred meters below the present-day land surface.

Chromite transformation in the course of more recent tectonic superficial modification under pneumatolytic or hydrothermal conditions has resulted in the striking colors of recent uvarovite, smaragdite, and kammererite formations which act as pathfinders in prospecting and exploring for chromite deposits. Table 5 shows some analyses of selected chromium ores.

Former Soviet Union. The former Soviet Union is one of the most important producers of chromium ore in the world. All the deposits are distributed in ultrabasite massifs in the Central and Southern Urals. The deposits that are most important at present were found in the late 1930s in the Akhtiubinsk region (North Kazakhstan). The Donskoye deposit, which is associated with the mining settlement of Khrom Tau, contains high-grade chromium ores for ferrochromium production and low-grade ores for chemical purposes. Mining is carried on in numerous open-pit mines, which implies that the ore bodies are small. A new open-cast mine was put into production near Donskoye, as is a processing plant with a throughput of 10^6 t/a. Strong prospection effort for new occurrences is being made in the Northern Urals, but because of the rough climate no mine has been opened up to 1986.

Bushveld. In the Bushveld (Republic of South Africa) mining began in the 1920s in two districts: the Lydenburg district (Eastern Bushveld) and the Rustenburg district (Western Bushveld).

From a geological and petrological point of view this is a large intrusion of 500×250 km with a thickness of over 5 km. The chromite "seams" are located in the pyroxenite – norite zone of the basal section of the intrusion, always below the platinum-bearing Merensky Reef. In the case of Rustenburg there are up to 25 chromite seams on top of each other. The thickness of the individual seams varies from a few centimeters to 1.80 m. The seams are workable from 0.35 m upward, especially if they can be combined into mining units (Cr_2O_3 content in the crude ore 30 – 40 %; Cr : Fe ratio = 1.6 – 2.3). In the Lydenburg district, which is genetically very similar to the Rustenburg district, only two seams are being mined; the Cr_2O_3 content is 44 % and the chromium : iron ratio 1.6 – 1.7. The iron content is frequently high, which may cause difficulties in the case of metallurgical ores; however, these ores are highly valued as chemical ores.

Great Dyke. The Great Dyke (Zimbabwe) is an intrusion which is 610 km long and 6 – 9 km thick – a remarkable length : thickness ratio which is unique in the world. The internal structure is similar to that of the Bushveld. From north to south, the individual complexes are Musengezi, Hartley, Selukwe, and Wedza. Selukwe

Table 5. Chemical analyses (mass fractions in %) of some chromium ores (crude ores, concentrates)

Country	Cr_2O_3	FeO	SiO_2	MgO	Al_2O_3	CaO	V_2O_5	Cr : Fe ratio

Table 6. Analysis of chromium ores from Zimbabwe

	Cr_2O_3 content, wt %	Cr : Fe ratio	Proportion, wt %
Metallurgical	over 48	over 2.8	80
Chemical	45 – 48	2.2 – 2.5	17
Refractory	42 – 46	1.8 – 2.0	3

consists of sack-like deposits containing 48 % Cr_2O_3 and even more, with a chromium : iron ratio greater than 2.8 (a highly valued metallurgical ore). In the Hartley region, on the other hand, numerous bands and seams 2 – 75 cm thick are being mined; these are separated by serpentinized peridotite layers, some of which are very thick and make mining very difficult. However, the Cr_2O_3 content varies between 48 and 57 %, and the chromium : iron ratio is over 2.8 (Table 6).

According to conservative estimates, 1 km^2 of the Great Dyke contains around 1.4×10^6 t of crude ore, which corresponds to assured reserves of 600×10^6 t (geologically 4.6×10^9 t are possible).

Other Ore Deposits

Madagascar. On the island of Madagascar, chromium ores are being mined since 1967 with an annual production of around 60 000 t of metallurgical grade ore. Total output is calculated to be almost 2×10^6 t since the beginning of the operation (50 – 52 % Cr_2O_3). The reserves are said to be around 5.5×10^6 t.

Turkey. Turkey still is the traditional country for chromite deposits of metallurgical quality, but because of falling prices on the world market and exhaustion of reserves, many mines have been forced to close. The most important regions belong essentially to the alpidic era, e.g., Bursa, Mugla district, and Elazig, including the Guleman chrome ore field. Open-pit mining, and

in some places underground mining at shallow depths, are employed.

Iran. Chromite deposits are described in two regions of Iran: northwest of Sabzawar near Mashad and 200 km northeast of the Gulf port of Bandar Abbas. These deposits are pocket-like, sometimes containing only 500 t of ore. Extraction is by open-pit mining and by primitive underground mining. Only hard lump ore for metallurgical applications is sometimes exported.

Philippines. On the Philippine island of Luzon the most important chromite deposits are to be found in the Coto region (near Masinloc, province of Zambales). These are chromite seams and pockets within layered dunites and harzburgites. They are classical metallurgical and refractory ores. More recently a new type of chrome ore has been put into production: chromite from lateritic soils. The concentrates are suited for the chemical industry.

Finland. In 1959 a fairly large deposit of chromite was discovered near Kemi, which has been developed into a productive mine. Chromium ore occurs in a serpentinite – anorthosite massif 12 km long and 1 – 2 km wide; the ore zone, however, is only 15 – 100 m thick and dips at an angle of 60° toward the north. The Cr_2O_3 content of the crude ore of the various ore bodies varies between 17.5 and 21.9 % (locally even up to 30.5 % Cr_2O_3); the chromium : iron ratio is low (0.81 – 1.87).

Former Yugoslavia. The deposits of chromite in former Yugoslavia are restricted to the Raduša massif near Skopje, but the mining of metallurgical ores there has fallen considerably. Native ores are being processed in a new plant, whereas ores imported from Albania are being processed in the old one. The chromium ores are always associated with serpentinized ultrabasites. The striated slab type predominates, but massive chrome ores are encountered in some places.

Albania. Since 1960, Albania has become the third largest producer in the world. All actual data are based on estimates because the Albanian government withholds production and export figures. Albanian deposits belong to the podiform type and normal grades are reported to be 43 % Cr_2O_3 with a Cr : Fe ratio of 3 : 1. The largest chrome ore mines are Bulquize and Matanesh with concentration plants of 300 000 t/a each.

2.2. Ore Beneficiation

The simplest method of concentrating chromite is by hand picking; this is still employed today at many pits, including those in Turkey, Brazil, Iran, and the Philippines. Because the mining of richer ores continues to decline, concentrating procedures, chiefly using the gravity method, have been developed to separate the serpentine from the chromite. For example, in South Africa or Brazil the chromite ores are enriched by crushing, milling, screening, and sophisticated gravity procedures. In South Africa, spirals and diamond pans are standard equipment. A combination of Reichert cones and Reichert spirals has also been employed. Although the costs are higher, the use of hydrocyclones for separating the fine chromite grains from waste is of great importance in the recycling of tailing dumps. Some chromium ores contain magnetite which can be removed by means of magnetic separation. However, if the magnetite is present as an individual phase within the chromite grains or as a fringe around the grains, this method is only suitable if Cr_2O_3 is further enriched. Flotation and electrostatic processes have so far enjoyed little success in the concentration of chromium ores. If the Cr_2O_3 content or the chromium : iron ratio is sufficient, fine-grained chromite concentrates can be briquetted or pelleted with the aid of binders.

The yield (65 – 85 % of the chromite actually contained in the crude ore) depends on many factors including the nature of the chromite – serpentine intergrowth, grain size, and Cr_2O_3 content of the ore or individual grain.

At the chromite concentration plant at Kemi in Finland a fraction of the crude ore (70 %) is crushed to below 10 mm in a primary crusher plant at the open-pit mine. After further grinding (rod and ball mill) and removal of sludge, the intermediate product is dried in a rotary kiln. The magnetic separation (a combination of weak and strong fields) produces two concentrates: concentrate 1 containing 45.9 % Cr_2O_3, which is

sold or used as molding sand, and concentrate 2 containing 42.0 % Cr_2O_3 for the production of ferrochromium.

3. Production of Sodium Dichromate

Directly or via several intermediate stages, sodium dichromate [*7789-12-0*], $Na_2Cr_2O_7 \cdot 2\,H_2O$, is the starting material for the production of all chromium compounds and pure chromium metal.

Sodium dichromate is made in a three-step process: (1) alkaline roast of chromite under oxidizing conditions (Eq. 1), (2) leaching, and (3) conversion of sodium monochromate to sodium dichromate by means of an acid (Eq. 2).

$$4\,FeO \cdot Cr_2O_3 + 8\,Na_2CO_3 + 7\,O_2 \xrightarrow{\text{ca. } 1000\,^\circ C} 8\,Na_2CrO_4 + 2\,Fe_2O_3 + 8\,CO_2 \quad (1)$$

$$2\,Na_2CrO_4 + 2\,H^+ \longrightarrow Na_2Cr_2O_7 + H_2O + 2\,Na^+ \quad (2)$$

3.1. Alkaline Roasting

Soda ash (sodium carbonate) is generally used as the alkali component but sodium hydroxide may also be employed [17–19]. The degree of solubilization of chromites by the roasting process depends on their composition. For optimum results, the process is controlled by adding so-called carrier materials. These ensure sufficient porosity of the material so that oxygen can diffuse into the roast. Porosity is maintained by means of such materials as iron oxide, bauxite, or dried leach residue; CO_2-emitting additives include lime and/or dolomite. The inert additives dilute the sodium carbonate and sodium chromate, which both melt at the reaction temperature. In the *low-lime process* the carbonates evolve CO_2, decrease the reaction temperature to below 1000 °C, and raise the melting point of the reaction products; the amount of lime added must be controlled so that the compound $5\,Na_2CrO_4 \cdot CaCrO_4$ [20] is produced in the roast. Temperatures above 1150 °C must be avoided because they result in the subsidiary components of the ore being attacked. At still higher temperatures the degree of conversion is markedly decreased. The optimum temperature range is very narrow and depends strongly on the type of ore used and the composition of the mixture.

Process Description. A typical roast mixture contains 100 parts of ore, 60 – 75 parts of sodium carbonate, 0 – 100 parts of lime or dolomite, and 50 – 200 parts of inert materials. The components are first finely ground, then mixed, and fed into the furnace. Annular hearth furnaces or rotary kilns are commonly used in large plants today.

The *annular hearth furnace* (Fig. 2) is made from steel with a refractory lining (inner diameter ca. 20 m; outer diameter ca. 30 m); it is driven by a gear wheel underneath and has rails running on rollers. The rotating hearth is sealed from the stationary parts of the furnace by sheets of metal dipping into annular water troughs. The furnace is heated by several burners from the side or from the top with gas, coal dust, or oil. The exhaust gas can be utilized to preheat the burner air or to generate steam. The mixture is fed to the outer edge of the annular hearth by a feed screw. A water-cooled ribbon screw transports the mixture inward, each time the annular hearth revolves, and finally removes it in the middle.

In the annular hearth furnace, the mixture is uniformly heated to the reaction temperature and made to travel toward the center of the hearth with a well-defined layer thickness. The furnace process is fairly independent of the sintering of the roast; it allows the production of melts that contain 40 wt % of water-soluble sodium chromate. The yield is 80 – 95 %, based on the chromite feed. The roast takes 2 – 6 h, depending on the composition of the mix.

Most of the kiln tube of the *rotary kiln* (Fig. 3) between the feed point and the reaction zone is used to heat the mixture. Shortly before the mix reaches the actual reaction zone, the soda melts and calcines. At this point the mixture bakes, and pellets or wreath-shaped cakes may be formed. If the furnace is operated inexpertly (temperature too high) or the composition of the mixture is wrong (too little carrier material) the kiln tube may get substantially clogged. In such cases, the constriction can be cleared by using an industrial gun.

The roast from the rotary kiln contains up to 30 wt % of water-soluble sodium chromate. The yield is 75 – 90 %, based on the chromite feed.

The roast takes 3 – 8 h, depending on the composition of the mixture. The hot exhaust gas from the rotary kiln can be used to preheat the burner air.

Gas Purification. Exhaust gas purification systems able to achieve a high degree of separation are required for dust collection. They essentially consist of two components: (1) an exhaust gas cooling system, with optional energy recovery, for example, steam generation; and (2) the exhaust gas purification system, usually an electrostatic separator. The size and the design of the purification system depend on the type of furnace. In the rotary kiln, ca. 10 % of the feed mixture is carried off by the exhaust gas, whereas in the annular hearth furnace, less than

1 % is carried off. However, operation of the annular hearth furnace necessitates a considerable expenditure on gas cooling.

Other Processes. In the literature, other processes are proposed but so far these have not achieved any industrial significance. Thus, attempts have been made to roast chromium ore in a shaft furnace [21] or in a fluidized-bed reactor [22]. A fundamentally different process involves the reaction of the chromium ore and soda in a molten salt mixture with oxygen-containing gases being injected [23].

3.2. Leaching of the Roast

After the oxidative process, the roast is a mixture of soluble salts and insoluble components. It contains sodium chromate, sodium aluminate, magnesium oxide, sodium vanadate(V), iron(III) oxide, unused alkali, unchanged chromite, and small amounts of sodium chloride originating from the soda.

When the roast is extracted with hot water, a pH of 10.5 – 11.2 results. The pH is controlled by adding acids or carbonates so that all chromate dissolves, whereas the alkali-soluble impurities hydrolyze and form a readily filterable precipitate along with the iron hydroxide and the unchanged ore components.

The roast is first cooled on a Fuller grate or in a cooling drum. Then it is either ground in a wet tube mill after addition of water or wash solution (see below) with carbonates or acids added, or it is dissolved in a stirred vessel. The insoluble residue is separated from the sodium chromate solution and thoroughly washed with a countercurrent of water. Continuous multistage Dorr plants or rotary filters are used; after separation, the insoluble residue is extracted two to three more times in counterflow. Dorr plants only exhibit satisfactory separation of residue and solution if the sodium chromate concentration is not too high. Rotary filter plants can be employed without difficulty for nearly saturated hot sodium chromate solutions; such filters are frequently preferred because the higher water consumption of the Dorr plant results in unnecessary steam costs in the subsequent evaporation process.

After removal of residual aluminum hydroxide and other undissolved components in a final purification process (e.g., thickener), the concentrated sodium chromate solution is acidified (Section 3.3).

Some of the filter residue is dried and added to the roasting mix (Section 3.1). The remainder is subjected to reducing treatment to convert the residual chromate content into an ecologically harmless form. To do this, the residue

is suspended in water and treated with sulfuric acid and sodium hydrogen sulfite or iron(II) sulfate; chromate residues are converted into chromium(III) compounds in this way. Subsequent addition of alkali precipitates trivalent chromium (and iron(III), if present) as hydroxide. The suspension is then filtered and the cake (optionally after further removal of water) is dumped.

3.3. Acidification

The sodium chromate solution is converted into sodium dichromate solution by acidification with sulfuric acid (Eq. 3) or carbon dioxide (Eq. 4). The sequence of individual steps depends on the acid.

$$2\,Na_2CrO_4 + H_2SO_4 \longrightarrow Na_2Cr_2O_7 + Na_2SO_4 + H_2O \quad (3)$$

$$2\,Na_2CrO_4 + 2\,CO_2 + H_2O \rightleftharpoons Na_2Cr_2O_7 + 2\,NaHCO_3 \quad (4)$$

Sulfuric Acid Acidification. Sulfuric acid is added to the concentrated sodium monochromate solution in an agitated vessel until the pH is about 4. The sodium dichromate solution is then concentrated in a continuous evaporation plant. Each liter of sodium dichromate solution yields 400 – 500 g of anhydrous crystalline sodium sulfate. The sulfate is removed by centrifugation. The clear, dark-red sodium dichromate solution contains 900 – 1200 g of $Na_2Cr_2O_7 \cdot 2\,H_2O$ per liter and additional small amounts of sodium sulfate; it is dispatched in tanks, e.g., of steel. The solution is either used directly as an oxidizing agent or processed to yield dichromate crystals.

Carbon Dioxide Acidification. After filtration the sodium monochromate solution from the first filtration stage is concentrated to ca. 850 g of Na_2CrO_4 per liter. The saturated sodium chromate solution is then acidified with a countercurrent of carbon dioxide at 0.5 – 1.5 MPa (5 – 10 bar) to yield sodium dichromate and sodium hydrogen carbonate. A series of stirred autoclaves is preferred for this reaction. They must be cooled to remove the heat of neutralization; the slurry leaves the last reactor at room temperature. The degree of conversion is about 80 – 90 %.

The sodium hydrogen carbonate is removed by centrifugation or filtration, preferably under pressure to prevent reaction (4) from being reversed. After it has been washed, water can be removed in a pusher centrifuge. Still moist, the sodium hydrogen carbonate is then transferred to a calcining furnace. The carbon dioxide produced in the furnace may be fed back to the acidification autoclaves [2]; the sodium carbonate obtained is recycled for alkaline ore roasting [24].

To obtain commercial sodium dichromate solution, further evaporation to a concentration of 1000 g of sodium dichromate per liter is required. This is then followed by a second acidification with carbon dioxide or sulfuric acid.

Production of soda is the main advantage of carbon dioxide acidification. However, this is offset by a number of difficulties, particularly the formation of deposits on the evaporator during the concentration of the sodium monochromate solution. Other problems include mastering the pressure technology and cooling, separation of the sodium hydrogen carbonate, yield loss due to reverse reaction, and clogging of the calcination furnace.

3.4. Crystallization

For the purpose of crystallization the sodium dichromate solution (950 – 1200 g/L) is further concentrated and may, if necessary, be filtered while hot to remove additional sodium sulfate or sodium chromate. It is then slowly cooled to 30 – 35 °C with constant stirring to obtain orange-red crystals of $Na_2Cr_2O_7 \cdot 2\,H_2O$.

Today continuous vacuum crystallization is carried out to an increasing extent. The initial difficulties of this process, particularly in obtaining coarse, dust-free crystals, have largely been overcome. The crystalline slurry is continuously separated from the mother liquor and dried. Precise control of the drying temperature is important because hydrated sodium dichromate is converted into anhydrous sodium dichromate above 84.6 °C and, therefore, cakes if overheated.

For reasons of occupational health, care should be taken to ensure that workplaces and production plants are dust free when sodium dichromate, especially the dried product, is being handled. In such locations, extensive venti-

lation and dust removal systems (wet scrubbers, electrostatic separators) are necessary.

4. Chromium Oxides

4.1. Chromium(III) Oxide and Chromium Hydroxide

Chromium(III) oxide [*1308-38-9*], Cr_2O_3, M_r 151.99, ϱ 5.2 g/cm^3, is green in finely dispersed form, whereas fairly large crystals have a blackish green hue and a metallic luster. The crystals have a hexagonal rhombohedral structure of the corundum type. The compound melts at 2435 °C, but begins to evaporate at 2000 °C to form clouds of green smoke; the boiling point is estimated to be 3000 – 4000 °C. The enthalpy of formation is − 1141 kJ/mol. Macrocrystalline chromium(III) oxide has a hardness of 9 on the Mohs scale. An amorphous form of the oxide is also known; this crystallizes on heating.

Chromium(III) oxide does not dissolve in water, acid, alkali, or alcohols. It is converted by a molten bath of sodium peroxide into soluble sodium monochromate(VI). Chromium(III) oxide and chromates(III) are used in organic chemistry as catalysts, e.g., in the hydrogenation of esters or aldehydes to form alcohols and in the cyclization of hydrocarbons. They also catalyze the formation of ammonia from hydrogen and nitrogen.

Production. The industrial production of chromium(III) oxide involves the reduction of solid sodium dichromate, generally with sulfur. The finely divided components are thoroughly mixed, fed into a brick-lined furnace, and brought to dark-red heat. The reaction proceeds exothermically. After the reaction mass has cooled, it is broken up and the sodium sulfate produced is leached out with water. The remaining solid is separated, rinsed, dried, and ground. To obtain 100 kg of chromium(III) oxide, 200 kg of sodium dichromate must react with at least 22 kg of sulfur; usually an excess of sulfur is used. Additives such as ammonium chloride or starch in the crude mixture affect the pigment properties. When sodium dichromate is replaced by the corresponding potassium salt, the hue of the pigment becomes more bluish.

The compound can also be prepared by a wet route involving reduction of sodium chromate by sulfur [25], with sodium thiosulfate being produced as a coproduct. The hydrate initially obtained is washed by decanting, filtered, and calcined to form the oxide.

Chromium(III) oxide destined for aluminothermic production of pure chromium metal must be heated additionally at 1000 °C to increase its grain size. If products particularly low in sulfur are to be produced for this purpose, charcoal can be used for the reduction instead of sulfur. High-purity oxides can also be obtained by thermal decomposition of chromium(VI) oxide or ammonium dichromate(VI), the latter yielding a material of very low density.

Chromium (III) oxide pigments contain 99.1 – 99.5 % Cr_2O_3. The aluminum oxide and silicon dioxide impurities each amount to ca. 0.1 %; the annealing loss at 1000 °C is about 0.3 %. The individual particles are spherical, with a diameter of 0.3 µm predominating. Chromium(III) oxide finds widespread application as a green pigment resistant to atmospheric conditions and heat. In addition, it is used as a colorant in glass products and printing inks, as a vitrifiable pigment in the ceramics industry, and as a polishing agent because of its considerable hardness (→ Pigments, Inorganic).

Chromium(III) Aquoxides [*12292-46-5*], [*12182-82-0*]. Pure chromium(III) hydroxide [*1308-14-1*], $Cr(OH)_3$, M_r 103.02, can only be prepared with difficulty because the hydrates initially obtained by precipitation are subject to aging.

After drying in air, specimens prepared by precipitation with alkali in the cold from violet chromium(III) salt solutions have a composition corresponding to $Cr_2O_3 \cdot 9\,H_2O$ [*12182-81-9*], and are usually formulated as $Cr(H_2O)_3(OH)_3$ [*41993-26-4*]. They are bright bluish green powders with limited life. All three hydroxyl groups react immediately with acids. Upon careful heating, dehydration occurs in steps and compounds containing 8, 5, 3, and 1 mol of water are formed. The density increases as the water content falls. Above 50 °C, conversion to a gelatinous green aging product occurs, and the solubility and chemical reactivity decrease; oxygen bridges are formed through the elimination of water, and polynuclear complexes are produced. The composition approaches that of chromium(III) oxide

hydroxide, CrO(OH) [*20770-05-2*]. Aging is accelerated by the presence of hydroxide ions.

In freshly precipitated hydroxides a crystalline phase isomorphic with bayerite [$Al(OH)_3$] is observed (→ Aluminum Oxide), whereas aged compounds are X-ray amorphous. The chromium(III) hydroxide hydrates are amphoteric compounds. With acids they form Cr^{3+} salts, whereas they dissolve in strong hydroxide solution to form chromates(III), e.g., the deep green sodium chromate(III), $Na_2Cr_2O_4$ (previously known as sodium chromite). When ammonium hydroxide is added, red solutions are formed. Oxidizing agents in the presence of alkali produce chromates(VI). With halogens this takes place immediately on gentle heating, but with oxygen several hours are required at a pressure of 4 MPa (40 bar) at 175 °C.

Chromium(III) hydroxide forms a stable colloid solution, whose isoelectric point is at pH 5. At higher pH the sol becomes negatively charged and adsorbs cations, whereas below pH 5 the charge is positive and anions are adsorbed. The adsorption capacity of chromium(III) hydroxide sols is higher than that of aluminum or iron(III) hydroxide sols. Sols containing 127 g of Cr_2O_3 per liter have been obtained from concentrated chromium(III) chloride solution by addition of ammonium carbonate and dialysis while the solution is hot [26].

Production. In industry chromium(III) hydroxide hydrates are usually produced from solutions of chromium(III) sulfate or chromium alum by precipitation with soda, sodium hydroxide solution, or ammonium hydroxide. Production by reduction of sodium chromate with sodium sulfide [27] has also been proposed.

For production from potassium chromium alum 54 kg of soda is dissolved in 300 L of water and a solution of 180 kg of alum in 900 L of water is added slowly. After the evolution of carbon dioxide has subsided, about 220 kg of moist chromium hydroxide containing 12 % Cr_2O_3 is obtained by filtration. Chromium(III) hydroxide hydrates are used for the production of chromium(III) salts by reaction with the corresponding acids.

Hydrated chromium(III) oxide, $Cr_2O_3 \cdot x\,H_2O$, is a brilliant emerald-green pigment known as Guignet's green [*12001-99-9*] that consists of very finely divided chromium(III) oxide to which water is bonded by adsorption. It is produced by heating a ground mixture of one part by weight of potassium dichromate and three parts by weight of boric acid in a muffle furnace to a faint red heat, which results in the formation of chromium(III) and potassium tetraborates. The molten mass still contains 6 – 7 % water and, after cooling, already has a deep green color. When this mass is boiled with water, it decomposes into chromium(III) oxide hydrate and boric acid. The product is coarse-grained and difficult to grind. Use of sodium dichromate as raw material results in a more yellowish color, whereas addition of thiourea or polysulfide to the reaction mixture produces a pigment with a bluish hue. The composition of the commercial products varies; typical values are: Cr_2O_3 79.3 – 82.5 %, H_2O 16.0 – 18.0 %, B_2O_3 1.5 –2.7 %.

Hydrated chromium oxide green is a pigment with properties similar to those of Guignet's green but with a somewhat less intensive coloration. This pigment is prepared by reducing sodium chromate or sodium dichromate in aqueous solution with sulfur or sodium formate in a stirred autoclave or pressure tube [28]. The temperature required is 250 – 270 °C. The solid is separated by filtration, washed, dried, and ground. The finished pigment consists of fine needles, with a particle size of 0.02×0.1 µm predominating. The product contains 79 – 80 % Cr_2O_3, the annealing loss is about 19 %, and the density 3.7 g/cm^3. The coloration changes at elevated temperature. Because of its high reflecting power at infrared wavelengths the product had at times been of special importance in camouflage paints.

4.2. Chromium(IV) Oxide (Chromium Dioxide)

Wöhler discovered ferromagnetic chromium dioxide in 1859 when he decomposed chromyl chloride [29]. About 100 years later, Du Pont produced it in pure form by decomposition of chromic acid under hydrothermal conditions [30], [31]. Industrial exploitation began after the morphological and magnetic properties had been modified by doping chromium dioxide with heavy metals [32], [33] in order to meet the requirements for a magnetic pigment [34]. The marketing of chromium dioxide at the begin-

ning of the seventies initiated the development of cobalt-doped iron oxides which are nowadays used as an alternative to chromium dioxide for information storage.

Physical and Chemical Properties [35]. Chromium dioxide [*12018-01-8*], CrO_2, M_r 84.00, crystallizes in black tetragonal needles. The lattice is of the rutile type and belongs to the space group 4/mmm. The dimensions of the unit cell are $a = b = 44.21$ nm and $c = 29.16$ nm. The X-ray density is 4.89 g/cm^3, and the phase width is between $CrO_{1.89}$ and $CrO_{2.02}$ [36]. The enthalpy of formation is -590 kJ/mol [37]. The temperature coefficient for the *c*-axis is negative [38]. At 100 °C, agglomerated blocks have a linear coefficient of expansion of -6×10^{-6} K^{-1} [39].

At room temperature chromium dioxide is ferromagnetic, the magnetic moment being 2 Bohr magnetons. The Curie temperature is 120 °C and increases to 155 °C as a result of doping with iron [40]. Finely crystalline needle-shaped chromium dioxide has a specific magnetic saturation M_s/ϱ of 77 – 92 A m^2/kg, whereas in single crystals M_s/ϱ rises to 100 A m^2/kg [32]. The magnetocrystalline anisotropy constant is 22×10^3 J/m^3 [41]. The coercivity H^c depends on the size of the crystals and on their shape and magnetocrystalline anisotropies. The coercivity is affected to differing extents by various heavy metals [42]. Iron, antimony, and tellurium increase H^c from 35 kA/m to 60 kA/m, whereas iridium increases it to 220 kA/m [43].

Chromium dioxide behaves as a metallic conductor [35], [44], with a specific electrical resistivity between 2.5×10^{-4} and 4×10^{-2} Ω cm [38], [45].

At room temperature and normal pressure chromium dioxide is metastable; when heated to temperatures above 350 °C, it decomposes into chromium(III) oxide and oxygen. Chromium dioxide has an oxidizing action on reactive organic compounds [46]; the reactivity is considerably decreased by enveloping it with iron(III) and chromium(III) oxides [47–49]. Chromium dioxide is insoluble in water. Reaction with water occurs at the crystal surface, with disproportionation to chromate and Cr^{3+} ions. The aqueous suspension has a pH of 3. However, chromium dioxide is soluble in concentrated sulfuric acid or concentrated alkali solution.

Production [50]. Chromium dioxide is made by decomposition of chromyl chloride, chromic acid anhydride [50], and chromium(III) chromate [51], or by oxidation of chromium(III) compounds with oxygen, hydrogen peroxide, chromic acid anhydride [52], or ammonium perchlorate [43].

Industrial production employs a process originally carried out under licence from Du Pont [42], which involves hydrothermal oxidation of chromium(III) oxide with excess chromic acid:

$$Cr_2O_3 + 3\,CrO_3 \longrightarrow 5\,CrO_2 + O_2$$

Iron(III) oxide and antimony(III) oxide are used as a dopant. Finely divided chromium(III) oxide is obtained either by thermal decomposition of ammonium dichromate or by dehydration of chromium(III) hydroxide [52].

A highly viscous paste (50 – 100 Pa · s) is produced by intensively homogenizing the starting materials. This paste is heated at 300 °C and 35 MPa (350 bar) to form a hard agglomerate of fine chromium dioxide needles which must be drilled out of the reactor trays, broken, and carefully ground. If the residual moisture exceeds 5 %, the product is reheated in a rotary kiln. The chromium dioxide is deagglomerated in an aqueous sodium sulfite suspension, and the crystal surface is simultaneously reduced; this forms a chromium(III) oxide hydroxide layer about 1 nm thick. To do this, the suspension is circulated through a mill which generates intense shear fields and the fine component is removed by using a hydrocyclone. After filtration and washing, drying is carried out in a spray tower. The chromium dioxide obtained has a bulk density of 0.8 g/cm^3.

Production is carried out to a large extent in closed equipment. Less than 2 mg of dust is emitted per 1 m^3 of exhaust air (STP). The chromium-containing wastewater from the production is worked up by reduction.

Use and Economic Importance. Chromium dioxide is used as a magnetic pigment. So far no other uses have achieved any significance [33].

In the audio field, chromium dioxide is used in mono- and multilayer tapes, the layers in the

latter containing chromium dioxide of different coercivity. In video tapes, it is employed either on its own or mixed with cobalt-doped iron oxides. Because of its low Curie point, chromium dioxide allows high-speed thermomagnetic copying of prerecorded audio and video tapes [53]. Chromium dioxide has been used in digital data storage since 1985. Since the magnetostriction of chromium dioxide is low, repeated playing results in virtually no level losses [54]. Table 7 contains data on chromium dioxide powder intended for various applications.

In 1984 the demand for magnetic pigments was about 50 000 t, about 10 % of this being chromium dioxide. The most important manufacturers are Du Pont (United States) and BASF (Federal Republic of Germany). In addition, there is a chromium dioxide plant in the former Soviet Union.

4.3. Chromium(VI) Oxide

Chromium trioxide [*1333-82-0*], chromic acid anhydride, chromic acid, CrO_3, M_r 99.99, ϱ 2.7 g/cm^3, forms dark red crystals which deliquesce in air. The enthalpy of formation is − 594.5 kJ/mol. The oxide melts at 198 °C and starts to decompose, giving off oxygen and brownish red vapors with a pungent smell. The rate of decomposition reaches a maximum at 290 °C, chromium(III) oxide, Cr_2O_3, being produced as the final product via various intermediate stages. Chromium(VI) oxide dissolves in water to form chromic acids (see 6.1); the solubility depends only slightly on temperature. A saturated solution contains 166 g of CrO_3 at 20 °C and 199 g of CrO_3 at 90 °C per 100 mL of water. The compound also dissolves in sulfuric acid and nitric acid. Chromium(VI) oxide is a powerful oxidizing agent, particularly in the presence of acids. Reactions with alkali metals and numerous organic compounds, e.g., low-boiling hydrocarbons, acetone, or benzene and its derivatives, proceed explosively with considerable heat being produced. Esters of chromic acid are also known, e.g., with such cyclic tertiary alcohols as methylfenchol and methylborneol.

Chromium(VI) oxide is made by the reaction of sodium dichromate with sulfuric acid. The reaction can be carried out with solid sodium dichromate or with solutions or suspensions. Both methods are in use industrially. The reaction proceeds rapidly and completely after the components have been mixed, with heat being evolved. Isolation of chromium(VI) oxide from the reaction mixture or purification of the crude product obtained from the aqueous solution is difficult. Quantitative separation of sodium hydrogen sulfate is possible only if the chromium(VI) oxide is melted, but at this temperature the product begins to decompose. The melting process must therefore be controlled very precisely.

Dry Process. Even today the old *discontinuous* process is in use to some extent. The reaction vessels are made from carbon steel or stainless steel. The conical containers are equipped with stirrer, exhaust facilities, and external heating. Sulfuric acid and sodium dichromate are added simultaneously with stirring. The paste heats up to 80 °C during mixing and is heated further

to evaporate water. At 170 °C sodium hydrogen sulfate melts, followed by chromium(VI) oxide at 198 °C. As soon as the reaction products are liquid, the heating and the stirrer are turned off. After a few minutes the heavier chromium(VI) oxide (ϱ 2.2 g/cm^3) settles at the bottom, and is covered by a layer of the lighter sodium hydrogen sulfate (ϱ 2.0 g/cm^3). Liquid chromium(VI) oxide is drawn off the bottom and conveyed to a cooling drum where it solidifies to form scales. Sodium hydrogen sulfate is subsequently drained. The yield of chromium(VI) oxide is about 85 %; 175 kg of sodium dichromate and 140 kg of 96 % sulfuric acid are required to obtain 100 kg of chromium(VI) oxide. About 150 kg of sodium hydrogen sulfate is obtained as byproduct.

Figure 4 shows a *continuous* dry process [55]. The raw materials are fed to a mixing screw for intimate mixing. A viscous paste of chromium(VI) oxide, sodium hydrogen sulfate, and water forms which is fed into a heated rotary kiln of stainless steel where it is melted. The heating must be controlled very carefully. The melt flows into a separator, where the heavier chromium(VI) oxide collects at the bottom of the trough, is removed by means of a rising pipe, and is converted into scales on cooling drums. The upper sodium hydrogen sulfate layer leaves the separating cell via an overflow and is also cooled on drums. Exhaust air from the various pieces of equipment is purified in a wash tower. The yield of this process is over 90 %.

Figure 4. Continuous production of chromium(VI) oxide a) Metering device; b) Wash tower; c) Mixer; d) Rotary kiln; e) Separation cell; f) Cooling drum for chromium(VI) oxide; g) Cooling drum for sodium hydrogen sulfate

If a highly concentrated solution is used instead of dichromate crystals, the kiln can be heated directly [56].

Wet Process. A hot saturated solution of sodium dichromate, which may still contain dichromate crystals, reacts with sulfuric acid [57]. In the course of 30 – 60 min the chromium(VI) oxide precipitates from the hot solution. On filtration a crude product is obtained, with a yield of about 80 %. Sodium hydrogen sulfate must be removed from the crude product by fusion. The filtrate can be recycled for converting sodium monochromate into dichromate; it can also be used in a fresh reaction mixture [58] if sodium hydrogen sulfate is first crystallized and removed at 20 – 25 °C. The crude chromium(VI) oxide is purified by continuous successive fusion and decanting [59].

As an alternative to production by reaction with sulfuric acid, Diamond – Shamrock developed an electrochemical process [60–62] in which chromic acid is produced from sodium dichromate in a two- or three-compartment cell.

Chromium trioxide is usually sold in the form of flakes, but the coarsely or finely ground product is also marketed. Good commercial products contain 99.5 – 99.7 % CrO_3 and a maximum of 0.1 % of sulfate. In the form of flakes, the product has a bulk density of 1.1 kg/L whereas that of the ground product is 1.4 kg/L. Steel drums must be used as containers and they must be tightly sealed because the product absorbs moisture from the air.

Chromium trioxide is classified as a dangerous substance in the EEC list and must be marked as fire-promoting and corrosive. In the IMDG code chromic acid has been put in class 5.1., UN No. 1463. The MAK of CrO_3 is 0.1 mg/m^3.

Electroplating is the most important field of application of chromium(VI) oxide. Numerous mixtures containing chromium trioxide are on the market; these "compounds" often contain hexafluorosilicates which improve the properties of the chromium coatings. Chromic acid solutions are also used for passivating zinc, aluminum, cadmium, and brass. Proprietary mixtures predominantly contain additions of fluoride, nitrate, and phosphate ions. Other uses for chromic acid are in the production of chromium dioxide and in wood preservation.

5. Chromium(III) Salts

5.1. General Properties

Water Content. In contrast to many other inorganic salts, chromium(III) salts occur in a variety of forms that depend on water content and on the particular conditions under which they are formed. Anhydrous compounds do not dissolve in pure water.

However, some of them, e.g., chromium(III) chloride or chromium(III) sulfate, dissolve in the presence of chromium(II) ions. In this process, one dissolved divalent ion transfers an electron via an anion bridge to a trivalent chromium ion in the solid crystal. Having become divalent, this ion detaches itself, acts in a similar manner on another chromium(III) ion in the crystal array, and reverts again to the trivalent state.

Complex Formation. Dissolved chromium(III) ions are always coordinated by various ligands. In the simplest case of the hexaaquochromium(III) ion, $[Cr(H_2O)_6]^{3+}$, six water molecules surround the central chromium ion in an octahedral arrangement as ligands. In addition to the aquo complexes, numerous coordination compounds with other molecules are known, and research on them, particularly studies of the ammine complexes (NH_3 as ligand), has played an important part in the development of coordination compound chemistry [63].

When negatively charged ligands enter the chromium complex, the charge is decreased appropriately. If the sum of the negative charges is four or more, the complex becomes anionic, an example of this being the diaquodisulfatochromium(III) ion $[Cr(SO_4)_2(H_2O)_2]^-$. In this case, each sulfate radical with a double negative charge occupies the position of two ligands.

The tendency of negatively charged ligands to form complex compounds with chromium increases in the following order:

$Cl^- < SO_4^{2-} < CH_3CO_2^- < HCO_2^- < OH^-$

Nitrato complexes are unknown.

Hydrate Isomerism. Chromium(III) complexes exhibit hydrate isomerism due to the positioning of anions and water molecules.

Thus chromium(III) chloride hexahydrate [*10060-12-5*] is known in three different forms:

1) Hexaaquochromium(III) chloride, $[Cr(H_2O)_6]Cl_3$, bluish grey
2) Pentaaquochlorochromium(III) chloride hydrate $[Cr(H_2O)_5Cl]Cl_2 \cdot H_2O$, bright green
3) Tetraaquodichlorochromium(III) chloride dihydrate $[Cr(H_2O)_4Cl_2]Cl \cdot 2\,H_2O$, dark green

The anions that are directly bound to the central atom do not dissociate in water and consequently do not react with the common precipitating agents; therefore, in the two green chlorides, only one-half and one-third of the chloride ions, respectively, are precipitated by silver nitrate.

Basic Salts. Hydroxide ions form coordinate bonds, with central ion of the hexaaquochromium complex being hydrolyzed. In this process, the pentaaquohydroxochromium(III) ion with a double positive charge is first formed:

$$[Cr(H_2O)_6]^{3+} \xrightarrow{OH^-} [Cr(H_2O)_5OH]^{2+} + H^+$$

When more alkali is added, chromium hydroxides are precipitated immediately. Finally, with a strong hydroxide solution, a soluble deep green hydroxo salt is produced:

$$Cr(OH)_3 + 3\,NaOH \longrightarrow Na_3[Cr(OH)_6]$$

Pentaaquohydroxochromium(III) complexes are very weak bases. Their salts hydrolyze and the pH of aqueous solutions usually is 2. The basicity of these salts is defined as the ratio of hydroxyl groups (in percent) bound to chromium to the number of hydroxyl groups in chromium(III) hydroxide, that could theoretically be bound to chromium. Pentaaquohydroxochromium(III) complexes therefore have a basicity of 33 %. When a second hydroxyl group enters the complex the basicity increases to 67 %. However, from a basicity of 60 % onward, chromium(III) hydroxide precipitates and these compounds are not used in practice.

5.2. Chromium(III) Sulfates and Chrome Tanning Agents

Chromium(III) Sulfate. *Anhydrous chromium sulfate* [*10101-53-8*], $Cr_2(SO_4)_3$, M_r

392.18, ϱ 3.0 g/cm^3, is a violet powder which is insoluble in water but dissolves to form complexes when reducing agents are added. For its preparation, chromium metal or chromite is heated over 250 °C with sulfuric acid.

The *octadecahydrate* [*13520-66-6*], $[Cr(H_2O)_6]_2(SO_4)_3 \cdot 6\,H_2O$, M_r 716.45, ϱ 1.86 g/cm^3, forms cubic crystals. The violet compound gives off water on heating and above 70 °C it is converted, with further loss of water, into a dark-green crystalline *pentadecahydrate* [*10031-37-5*]. As the water content diminishes, the solubility decreases.

*Solutions*of chromium(III) sulfates can be made by treating chromite with sulfuric acid in the presence of chromium(VI) compounds [64]. Since other components of the ore are solubilized at the same time, the solutions are strongly contaminated; separation of magnesium, aluminum, and iron presents such great difficulties that this process has not yet gone beyond the experimental scale. Chromium(III) sulfate solutions are also obtained by dissolving ferrochromium in sulfuric acid, a process in which iron(II) sulfate is obtained as a coproduct. So far, the economical preparation of a pure product has been only partially successful.

Large quantities of chromium(III) sulfate solution are produced in the oxidation of organic substances with chromic acid or sodium dichromate in sulfuric acid solution. Examples of this are the preparation of anthraquinone from anthracene, the preparation of benzoquinone from aniline, or the bleaching of montan wax. These solutions are used to produce other chromium products; an electrolytic regeneration to dichromate is also possible.

Tanning Agents. *Basic chromium(III) sulfates* are used on a large scale as tanning agents for leather. Industrially, two processes are available for the reduction of sodium dichromate: (1) reaction with organic compounds (molasses, sugar) in the presence of sulfuric acid and (2) reduction with sulfur dioxide.

Reduction with molasses is carried out in aqueous solution; about 30 kg of molasses or 15 kg of cane sugar is required for 100 kg of sodium dichromate dihydrate. The amount of sulfuric acid required depends on the desired basicity. To adjust the basicity to 33 %, about 103 kg of 96 % acid is needed. The reaction is strongly exothermic; water evaporates in abundance and must be continuously replenished. Lead-lined vats have proved successful as reaction vessels. The exhaust gases have an unpleasant smell, but this can be eliminated by scrubbing with water in a wash tower or by heating them after condensing the water vapor.

The properties of the final product are, to a certain extent, dependent on how the reaction is performed. If sulfuric acid is added first to the dichromate solution and the reducing agent is then added slowly, relatively few organic acids are produced as result of side reactions. The proportion of these acids becomes considerably larger if the dichromate solution is mixed first with the reducing agent and the sulfuric acid is added last. The organic acids form chromium complexes and mask the tanning agent. This masking delays the tanning process.

In the *reduction with sulfur dioxide* sulfuric acid is generated in such proportions that the tanning agent produced has a basicity of 33 %. For the reduction of 100 kg of sodium dichromate dihydrate, 65 kg of SO_2 is theoretically required.

The reaction is carried out in lead-lined or brick-lined absorption towers containing ceramic packing material. Sulfur dioxide is produced by combustion of liquid sulfur which yields a gas containing 8 – 18 % SO_2; SO_2-containing gases from other manufacturing processes are also suitable for the reaction.

For the production of chrome tanning agents, chromium(III) sulfate solutions which are generated in the manufacture of organic intermediates may also be used. Impurities must be removed from such solutions, and the solutions are then converted to the correct basicity by acidification or neutralization. They must also be concentrated by evaporation.

To manufacture *solid tanning agents,* the concentrated solutions are dried in spray driers made of stainless steel. With a basicity of 33 %, the amorphous green powder obtained generally contains 24 – 26 % Cr_2O_3, 25 – 27 % SO_3, 22 – 25 % Na_2SO_4, and 22 – 25 % water. In air, the powder absorbs moisture and the particles stick together. Under the microscope, the individual particles, which are often hollow spheres or fragments of such spheres, have a glassy appearance.

The product obtained by spray drying is sold under numerous trade names, e.g., Chrometan (British Chrome and Chemicals, UK); Chromi-

tan (BASF, Federal Republic of Germany); Chromosal (Bayer, Federal Republic of Germany); Salcromo (Stoppani, Italy); Tanolin (Hamblett & Hayes Co., Mass., USA).

Paper or jute sacks with watertight polyethylene liners or wrappings, or plastic sacks are used for packing.

Solutions of basic chromium(III) sulfate containing 12 – 18 % Cr_2O_3 are also available commercially. Solutions of higher concentration must be kept warm because sodium sulfate precipitates at room temperature. The solutions are transported in rubber-lined rail or road tankers; lead-lined tankers are also suitable.

Besides the standard 33 % basic type, a large number of products of higher basicity are available. To improve their stability toward alkali, these contain various quantities of organic acids. The market importance of chrome tanning agents containing 30 % chromium oxide and having a basicity of 50 % has increased.

In addition to the standard products, mixtures of chrome tanning agents have established themselves on the market. These contain basifying agents which react slowly and eliminate the need for the tedious basifying process. Mixed products containing special organic masking agents and having a high total basicity have been developed. These are used in combination with conventional chrome tanning agents and afford a high degree of chromium exhaustion in the liquors.

Potassium chromium(III) sulfate [*10141-00-1*], [*10279-63-7*], [*7788-99-0*], potassium chrome alum, $KCr(SO_4)_2 \cdot 12\,H_2O$, M_r 499.11, ϱ 1.813 g/cm^3, crystallizes in the cubic system forming violet regular octahedra which decay in air and melt at 89 °C, the color changing to green; the enthalpy of formation is − 5788 kJ/mol. The solubility in water at 25 °C is 11.1 wt %. The solution is violet when cold, but becomes green above 50 °C, this change being accompanied by a decrease in the molar conductance. For 0.125 M solution at 50 °C, the molar conductance is 221 Ω^{-1} cm^2 mol^{-1} for the violet form and 202 Ω^{-1} cm^2 mol^{-1} for the green form. This change is reversible and its rate is increased by acids. The green form always occurs as an amorphous solid and crystals are unknown.

In addition to the alum containing 12 molecules of water of crystallization, potassium chromium(III) sulfates containing one [*35177-45-8*], two [*35177-44-7*], and six [*35177-43-6*] molecules of water are known.

For the preparation of potassium chromium alum, a saturated potassium dichromate solution is reduced with sulfur dioxide in the presence of sulfuric acid.

During the reaction, the temperature must be kept below 40 °C by cooling to prevent the green modification being produced. Apart from sulfur dioxide, such organic compounds as formaldehyde, methanol, or starch are suitable as reducing agents. Crystallization starts after sulfuric acid has been added and the temperature is kept further below 40 °C. If the solution is allowed to settle in vats, large crystals are produced, whereas fine ones result if the solution is stirred. The industrial product contains 15 % Cr_2O_3 and 0.01 – 0.03 % Fe. The mother liquor may be reused in the production of the alum solution, but after several cycles it is so enriched in magnesium and sodium sulfate that crystallization of the alum is retarded. The trivalent chromium is then precipitated from the solution with alkali and may be recycled. Lead-lined equipment is used for the production.

The alum can also be prepared from ferrochromium. The reaction with sulfuric acid first results in a solution of chromium(III) and iron(II) sulfates. The majority of the iron(II) sulfate can be removed by crystallization. With potassium sulfate added, the filtrate yields the alum which is contaminated with 0.1 – 0.2 % Fe.

Potassium chrome alum was formerly used on a large scale as a tanning agent in the leather industry, but its importance in this field has receded with the introduction of the basic chromium sulfates. Other fields of application are the textile industry and the film and photographic industry.

Ammonium chromium(III) sulfate [*10141-00-1*], ammonium chrome alum, $NH_4Cr(SO_4)_2 \cdot 12\,H_2O$, M_r 478.47, ϱ 1.72 g/cm^3, crystallizes in the cubic system forming bluish violet octahedra which appear ruby red when held against the light and slowly decay in air. When heated to 70 °C they turn green, and at 94 °C the compound melts in its water of crystallization. Ammonium chrome alum is obtained from chromium(III) sulfate solutions by addition of a stoichiometric amount of ammonium sulfate. Ammonium chrome alum

crystallizes much more easily than potassium chrome alum. The preparation of ammonium chrome alum from carbon-rich ferrochromium has assumed relatively great importance in the electrochemical production of pure chromium metal [65].

5.3. Other Chromium(III) Salts

Chromium(III) fluoride [*7788-97-8*], CrF_3, M_r 108.99, ϱ 3.8 g/cm^3. The anhydrous compound forms highly refractive rhombohedral crystals. It melts above 1000 °C and is distinctly volatile between 1100 and 1200 °C. Chromium(III) fluoride is insoluble in water if no divalent chromium is present. Double compounds are formed with other metal fluorides, e.g., green $CrF_3 \cdot 2\,KF \cdot H_2O$.

Hydrates are known which contain three [*16671-27-5*] to nine [*68374-27-6*] molecules of water. The violet hexaaquochromium(III) fluoride, $[Cr(H_2O)_6]F_3$, and its trihydrate, $[Cr(H_2O)_6]F_3 \cdot 3\,H_2O$, can be obtained from hexaaquochromium(III) salt solutions and alkali fluorides. Products containing less water are green. The composition of the industrial product corresponds approximately to $CrF_3 \cdot 3.5\,H_2O$ and the product contains about 30 % chromium.

For the production of chromium(III) fluoride hydrate, chromium(III) oxide hydrate is dissolved in hot aqueous hydrofluoric acid and the green salt crystallizes. Chromium(III) fluoride is used in the textile industry for mordanting wool, for chromating dyestuffs, and in vigoureux printing. Chromium(III) fluorides have also found application in rust-prevention paints as corrosion inhibitors.

Chromium(III) Chloride.

Anhydrous chromium(III) chloride [*10025-73-7*], $CrCl_3$, M_r 158.36, forms hexagonal reddish violet flakes which sublime at 950 °C yielding a vapor that dissociates above 1300 °C. The enthalpy of formation is −554.8 kJ/mol. Chromium(III) chloride is insoluble in water if no reducing agent is present. On roasting in air, chromium(III) oxide is produced.

Anhydrous chromium(III) chloride is obtained along with iron(II) chloride by chlorinating roasting of chromite in the presence of carbon at 900–1050 °C [66]. Oxygen is added to the chlorine to prevent nonvolatile residues, in particular minor constituents of the ore, from sintering together. Fractionating condensation between 400 and 640 °C has been suggested for separating the chloride vapors [67]. The compound can also be obtained by chlorinating chromium(III) oxide in the presence of reducing agents or by treating ferrochromium with chlorine [68].

Chromium(III) chloride can be prepared readily from chromyl chloride by reaction with carbon monoxide and chlorine. The reaction proceeds rapidly in the gas phase at 750–850 °C [69]. Since chromium(III) chloride evaporates only at a higher temperature, a considerable portion of the product, which varies as a function of the partial pressure, is produced in the form of fine crystals. As the smoke cools down, these act as crystallization nuclei for any gaseous chromium(III) chloride still present. This procedure prevents the deposition of solid on the cooling surfaces.

Anhydrous chromium(III) chloride has been suggested for chromizing steel parts by surface diffusion; it can be used for the production of high-purity ductile chromium metal by reduction with magnesium and for the synthesis of organic chromium compounds.

Chromium(III) chloride hexahydrate [*10060-12-5*] is obtained in pure form by introducing hydrogen chloride and methanol into an aqueous solution of chromic acid. The reaction proceeds exothermally, and adequate cooling must be provided. Of the three isomeric hydrates (see 5.1) the dihydrate of the tetraaquodichlorochromium(III) chloride crystallizes in the cold. This is used as an intermediate in the production of chromium complex dyes and other chromium salts, e.g., chromium stearates, which are of interest as impregnating agents for textiles or paper. The solution is also used as a mordant in the textile industry.

Chromium(III) Acetate [*1066-30-4*]. The bluish violet hexaaquo salt [*66851-10-3*], $[Cr(H_2O)_6](CH_3COO)_3$, M_r 337.22, forms needle-shaped crystals. Basic chromium(III) acetates are green. For their preparation chromium(III) hydroxide hydrate is dissolved in dilute acetic acid, and the solid is obtained by drying on drums or in a spray drier. Basic chromium acetates are used as mordants

in calico printing and worsted top printing, and also for fixing vigoureux dyes. Combinations of basic chromium(III) acetate and basic chromium(III) formate also find application in the textile industry as mordants. In addition, chromium(III) acetate is used as a starting compound in the production of organic chromium dyes.

Chromium(III) Nitrate [*13548-38-4*]. Normally, chromium(III) nitrate crystallizes with nine molecules of water, $[Cr(H_2O)_6](NO_3)_3 \cdot 3\,H_2O$ [*7789-02-8*], M_r 400.15, ϱ 1.8 g/cm^3. The dark violet rhombic prisms become green above 36 °C and melt at 66 °C. The nitrate group is not bound to the trivalent chromium in a coordination compound. The salt is readily soluble in water, acid, alkali, and alcohol. To prepare chromium(III) nitrate, chromium(III) oxide hydrate is dissolved in nitric acid and the nitrate is allowed to crystallize. The compound is also produced by reduction of chromic acid with methanol in the presence of nitric acid. During the exothermal reaction, the temperature is kept between 55 and 65 °C by cooling. Chromium(III) nitrate is used to a limited extent as a mordant in cotton printing, usually together with basic chromium acetates. In addition, the salt is suitable for producing alkali-free catalysts.

Chromium(III) Phosphate. *Anhydrous chromium(III) phosphate* [*7789-04-0*], $CrPO_4$, M_r 146.97, ϱ 2.99 g/cm^3, is a black powder which belongs to the orthorhombic crystal system. It is insoluble in water, hydrochloric acid, and aqua regia but is attacked by boiling sulfuric acid. It is obtained by calcining its hydrates. The violet *hexahydrate* [*13475-98-4*], $[Cr(H_2O)_6]PO_4$, M_r 255.06, ϱ 2.12 g/cm^3, precipitates from chromium(III) salt solutions upon addition of phosphoric acid and disodium hydrogen phosphate. The crystals are triclinic and only sparingly soluble in water. Green chromium(III) phosphates precipitated hot contain two to three molecules of water after drying. A salt containing four molecules of water is also known. The green products are virtually insoluble in water. They are used to a small extent as pigments and have corrosion-inhibiting properties.

Chromium lignosulfonates [*9066-50-6*] are prepared by reaction of sulfite waste liquor from the pulp industry with sodium dichromate solution, the hexavalent chromium being reduced by the organic material to trivalent chromium. After filtration, the pH is adjusted by means of alkali and the product is dried in spray driers. It is a free-flowing, water-soluble powder and normally contains cations in the following quantities: ammonium 1.5 – 2.5 %, chromium 2.5 – 4.2 %, iron 0 – 5 %, and sodium 1.5 – 2.5 %. These saltlike compounds are used to a large extent in the petroleum industry as additives for lowering the viscosity of drilling muds and decreasing liquid loss [70].

6. Chromic Acids and Chromates(VI)

6.1. Chromic Acids

Chromic acids are not known in the free state. Depending on the method of preparation, mono-, di-, tri-, or tetrachromic acids are formed in aqueous solution. In alkaline or dilute solution, formation of the yellow monochromate ion is favored, but in acid solution or at high concentrations, the orange-red dichromate ion is formed preferentially. Aqueous solutions of chromic acids are, therefore, yellow or red depending on their concentrations. Figure 5 shows the density as a function of concentration.

Figure 5. Density of aqueous chromic acid solutions at 15.6 °C (60 °F)

Dissociation constants (at 25 °C) are as follows:

$$H_2CrO_4 \rightleftharpoons H^+ + HCrO_4^- \quad K_1 = 1.21$$

$$HCrO_4^- \rightleftharpoons H^+ + CrO_4^{2-} \quad K_2 = 3.7 \times 10^{-7}$$

$$H_2Cr_2O_7 \rightleftharpoons H^+ + HCr_2O_7^- \quad K_3 = 1$$

$$HCr_2O_7^- \rightleftharpoons H^+ + Cr_2O_7^{2-} \quad K_4 = 0.85$$

$$Cr_2O_7^{2-} + H_2O \rightleftharpoons 2\,H^+ + 2\,CrO_4^{2-} \quad K_5 = 3 \times 10^{-15}$$

$$Cr_2O_7^{2-} + H_2O \rightleftharpoons 2\,HCrO_4^- \quad K_6 = 0.023$$

The standard redox potential for the reaction

$$Cr_2O_7^{2-} + 14\,H^+ + 6\,e \rightleftharpoons 2\,Cr^{3+} + 7\,H_2O$$

is 1.36 V.

Chromic acid solutions are strong oxidizing agents with a strongly acidic character; they form salts with metals and bases. The monochromates(VI), M_2CrO_4, which are derived from chromic acid, hydrolyze in aqueous solution:

$$CrO_4^{2-} + H_2O \rightleftharpoons HCrO_4^- + OH^-$$

The easiest method of preparing chromic acid solutions is to dissolve chromium(VI) oxide in water. In industry, chromic acid is often produced from sodium dichromate(VI) and sulfuric acid.

Chromic acid solutions can also be prepared by anodic oxidation of chromium(III) sulfate solutions [71]; lead-lined cells with a diaphragm and lead electrodes are employed. To keep the concentration of sulfuric acid constant, the chromium(III) sulfate solution is introduced first into the cathode space, where it becomes depleted of sulfuric acid, and then into the anode space. Here, oxidation to chromic acid takes place and the concentration of sulfuric acid is restored to its original value.

In practice, several electrolytic cells are combined to form a unit. At a current density of 3 A/dm^2 the voltage is 3.5 V. Current efficiency is 80 %. Lost chromium is periodically replenished by adding chromium(III) oxide. The electrolytic preparation of chromic acid can also start from chromium hydroxide hydrate with chromic acid as electrolyte [72].

Aqueous chromic acid solutions are used as pickling and chromium-plating baths in the metal processing and plastics processing industries.

6.2. Alkali Chromates and Dichromates

Sodium chromate [*7775-11-3*], Na_2CrO_4, M_r 161.97, *mp* 792 °C, ϱ 2.723 g/cm^3, ΔH^0_{298} −1329 kJ/mol, crystallizes in the orthorhombic system in small yellow needles or columns; transformation to the hexagonal form takes place at 413 °C. The bulk density of the powder is 0.7 g/cm^3; that of the crystals is 1.67 g/cm^3. For solubility, see Table 8. The compound is hygroscopic and forms several hydrates: below 19.5 °C the decahydrate [*13517-17-4*]; between 19.5 and 25.9 °C, the hexahydrate; and between 25.9 and 62.8 °C, the tetrahydrate [*10034-82-9*] which undergoes transformation into anhydrous sodium chromate above 62.8 °C.

To prepare the salt, sodium dichromate solution is usually mixed with a stoichiometric amount of sodium hydroxide, and the salt solution is then crystallized or spray dried. The 96.5 – 98.5 % product (0.4 % NaCl, 2 % Na_2SO_4) is stored and dispatched in watertight steel drums.

Sodium chromate is used as a corrosion inhibitor in the petroleum industry and as a dyeing auxiliary in the textile industry.

Sodium Dichromate. The *dihydrate* [*7789-12-0*], $Na_2Cr_2O_7 \cdot 2\,H_2O$, M_r298.0, ϱ 2.348 g/cm^3, ΔH°_{298} − 2194 kJ/mol, forms orange-red, monoclinic, translucent needles which are converted into the anhydrous salt above 84.6 °C. The bulk density is 1.2 g/cm^3. For solubility, see Table 8. The heat of solution is − 118 kJ/kg. The compound is very hygroscopic and deliquesces in air; in acid solution, it is a strong oxidizing agent.

The preparation of sodium dichromate is described in Chapter 3.

Sodium dichromate is the most important of the industrial chromium chemicals and is used as the starting compound for almost all chromium compounds. Large quantities are used in numerous industrial fields. In the textile industry (wool, cotton, silk, and synthetics), sodium dichromate is used in mordanting and in aftertreatment baths. The leather industry virtually no longer uses sodium dichromate. Sodium dichromate has a variety of uses in the surface treatment of metals, e.g., in the pickling of steel, aluminum, magnesium, and other metals and

Table 8. Solubility (in wt %) of various chromates in water

	Temperature, °C								
	0	20	25	40	50	60	75	80	100
Sodium chromate		44.3		48.8		53.5		55.8	56.1
Sodium dichromate dihydrate	70.6	73.18		77.09		82.04		88.39	91.43
Potassium chromate		39.96							45.0
Potassium dichromate	4.3	11.7		20.9		31.3		42.0	50.2
Ammonium chromate	19.78		27.02		34.4		41.2		
Ammonium dichromate	15.16	26.67		36.99		46.14		54.10	60.89
Silver chromate		0.0025			0.0053				0.0041

their alloys. The ability of the chromates to convert gelatin or protein into an insoluble form on exposure to light is exploited on a large scale in printing technology (lithography). A further field of application for the dichromates is in corrosion protection; they are added to crude oil in pipelines and to water in closed cooling systems as direct corrosion inhibitors. Sodium dichromate is also used for the manufacture of wood preservatives.

In the chemical industry, sodium dichromate is used as a strong oxidizing agent in numerous cases; the most important include oxidation of anthracene to anthraquinone (dyes), of aniline to quinone (hydroquinone for the photographic industry), of camphene to camphor, and of contaminants in oils, fats, tallow, and waxes (soap industry, wax bleaching).

To these classical applications, the wide field of catalysts and catalyst carriers containing chromium(III) oxide or chromates has been added over the past thirty years. These are important in a variety of oxidation and carbonizing processes.

Anhydrous sodium dichromate [*10588-01-9*], $Na_2Cr_2O_7$, M_r 261.96, *mp* 356.7 °C, ϱ 2.52 g/cm^3, bulk density 1 g/cm^3, heat of solution ca. − 33.5 kJ/kg, forms light-brown to orange-red plates which are strongly hygroscopic. They decompose above 400 °C with the formation of sodium monochromate(VI), chromium(III) oxide, and oxygen.

Anhydrous sodium dichromate can be prepared by melting down sodium dichromate dihydrate, by crystallizing aqueous dichromate solutions above 86 °C, or by drying sodium dichromate solutions in spray driers.

Anhydrous sodium dichromate is required for cases in which the water content of the dihydrate has an interfering action. Thus, for example, the energy liberated in the oxidation with anhydrous sodium dichromate is greater than that liberated in the case of sodium dichromate dihydrate. Anhydrous sodium dichromate is, therefore, used in the preparation of chromium(III) oxide by the dry process (4.1), in pyrotechnics, and in anhydrous oxidation processes where it replaces the more expensive potassium dichromate. Compared with sodium dichromate dihydrate, anhydrous sodium dichromate has the advantage that it can first absorb two molecules of water (13 wt %) instead of deliquescing immediately when moisture is admitted.

Potassium chromate [*7789-00-6*], K_2CrO_4, M_r 194.2, *mp* 968.3 °C, ϱ 2.73 g/cm^3, ΔH^0_{298} − 1383 kJ/mol, occurs as the stable β-modification. The lemon-yellow, nonhygroscopic prisms are isostructural with K_2SO_4. At 666 °C they are converted into hexagonal α-potassium chromate. For solubility, see Table 8. The heat of solution is −71.3 kJ/kg. The salt crystallizes from aqueous solution in anhydrous form and is thermally stable.

Potassium chromate is obtained by reacting potash with potassium dichromate. The potassium salt has been supplanted nearly completely by the cheaper sodium chromate and is used only for very specific purposes such as in the photographic industry.

Potassium dichromate [*7778-50-9*], $K_2Cr_2O_7$, M_r 294.19, *mp* 397.5 °C, occurs in two modifications. α-$K_2Cr_2O_7$, tabular or prismatic, bright orange-red triclinic crystals, ϱ 2.676 g/cm^3, has a bulk density of about 1.3 – 1.6 g/cm^3; at 241.6 °C α-$K_2Cr_2O_7$ transforms to β-$K_2Cr_2O_7$. For solubility, see Table 8. The heat of solution is − 258.3 kJ/kg. The thermodynamic data

are as follows: c_p 219.7 J mol^{-1} K^{-1}, ΔH°_{298} − 2033 kJ/mol, S° 291.2 J mol^{-1} K^{-1}, heat of fusion 36.7 kJ/mol. The substance is not hygroscopic and, above the melting point, decomposes into potassium chromate, chromium oxides, and oxygen.

Today potassium dichromate is obtained primarily by conversion of sodium dichromate with potassium chloride. Potassium dichromate has largely been supplanted by the cheaper sodium dichromate but is still used whenever its advantage of being nonhygroscopic is important, for example, in the match, firework, film, and photographic industries. Potassium dichromate is of interest in the preparation of yellow and green zinc pigments (→ Pigments, Inorganic).

Ammonium chromate [*7788-98-9*], $(NH_4)_2CrO_4$, M_r 152.07, smells of ammonia and forms golden yellow needles, ϱ 1.886 g/cm^3, ΔH^0_{298} − 1152 kJ/mol, S^0_{298} 656 J mol^{-1} K^{-1}. For solubility, see Table 8. In air, it decomposes into ammonia, water, and ammonium dichromate. On heating it ignites and decomposes into chromium(III) oxide, ammonia, and nitrogen. Ammonium chromate is prepared from ammonium dichromate with the addition of ammonia.

Ammonium dichromate [*7789-09-5*], $(NH_4)_2Cr_2O_7$, M_r252.06, forms large, bright orange-red crystals, ϱ 2.155 g/cm^3, bulk density ca. 1.0 – 1.3 g/cm^3. For solubility, see Table 8. The heat of solution is − 230.9 kJ/mol. Ammonium dichromate crystallizes in anhydrous form from aqueous solution and is not hygroscopic. Decomposition, which is not preceded by melting, sets in on heating to 180 °C; this becomes self-maintaining at 225 °C and above. Decomposition proceeds with displays of fire and heat, and large amounts of gas are developed. The products of decomposition are chromium(III) oxide, nitrogen, and water vapor. Ammonium dichromate reacts very violently with organic solvents.

Ammonium dichromate is prepared by reaction of sodium dichromate with ammonium chloride or, less frequently, ammonium sulfate. Ammonium dichromate is used as the starting material for preparing very finely divided chromium(III) oxide and, in addition, finds application primarily in pyrotechnics, wood preservation, and photography (lithography) for the preparation of light-sensitive solutions of gelatin or proteins. Ammonium dichromate is also used to prepare catalysts for organic syntheses. A further field of application is the production of magnetic chromium(IV) oxide. Because of its self-ignition properties and explosiveness, ammonium dichromate is subject to the German Explosives Law and the IMDG code, class 5.1, UN No. 1439. It is also distributed moist.

6.3. Other Chromates

Barium chromate [*10294-40-3*], $BaCrO_4$, M_r 253.33, *mp* 1400 °C (decomp.), ϱ 4.498 g/cm^3, ΔH^0_{298} − 1156 kJ/mol, crystallizes as light-yellow transparent rhombic crystals which are isomorphous with barium sulfate. Barium chromate is only sparingly soluble in water but dissolves readily in acids.

In the presence of excess alkali chromate or dichromate, barium chromate has a tendency to form double salts, among which special mention may be made of potassium barium chromate [*13819-19-7*], $K_2CrO_4 \cdot BaCrO_4$, and ammonium barium chromate [*13819-20-0*], $(NH_4)_2CrO_4 \cdot BaCrO_4$, both of which are light yellow.

These barium chromate double salts can be prepared by reaction of soluble barium salts or barium hydroxide with alkali chromate(VI) or dichromate(VI). In weakly acid solutions, as is the case, for example, if dichromates(VI) are used, the precipitation is incomplete. Quantitative precipitation is achieved by adding sodium acetate.

Yellow barium chromate and its double salts can be used for the production of chrome pigments for paints; the double salts, in particular, are excellent corrosion protection paints for all metals. They form sparingly soluble metal chromates, which prevent attack by moisture (condensation, seawater) even more readily than zinc chromate.

Calcium chromate [*13765-19-0*], $CaCrO_4$, M_r 156.07, *mp* 1020 °C (decomp.), ϱ 3.12 g/cm^3, is a yellow powder which is sparingly soluble in water (4.3 wt % at 0 °C, 0.42 wt % at 100 °C). The compound has acquired no industrial importance, but its prepara-

tion directly from chromium ores is described in several patents [73], [74].

Calcium dichromate [*14307-33-6*], $CaCr_2O_7$, M_r 256.06, ΔH^0_{298} −1821 kJ/mol, is thought not to constitute a uniform crystalline phase but to be a mixture of phases consisting of calcium monochromate and chromium(VI) oxide. The compound forms a series of readily soluble hydrates. Thus, below 10 °C, the hexahydrate $CaCr_2O_7 \cdot 6\,H_2O$ exists; between 20 and 40 °C, the pentahydrate [*61204-19-1*]; between 50 and 60 °C, the tetrahydrate; and above 70 °C, the monohydrate [*85752-77-8*]. A red deliquescent calcium dichromate trihydrate has also been prepared from the tetrahydrate.

Calcium dichromate can be made industrially by oxidative roasting of chromium-containing ores with calcium carbonate or calcium oxide and subsequent leaching of the cake with an acid, e.g., chromic or sulfuric acid [74].

Copper Chromates. Neutral copper chromate [*13548-42-0*], $CuCrO_4$, M_r 179.53, is produced as a yellowish brown, water-containing compound by precipitation from a copper sulfate solution with sodium or potassium dichromate. The compound is used as the starting material for "chrome black" which is prepared by calcining the neutral salt under oxidizing conditions and subsequently leaching with hydrochloric acid.

The double salt *copper ammonium chromate* (cupric ammonium chromate) is required in dyeworks along with logwood and fustic extracts to obtain olive green wool or cotton dyes. Copper chromate is used as such or in reduced form as a catalyst in a number of petrochemical reactions.

Iron Chromates. No anhydrous iron(II) chromate is known. On the other hand, the watersoluble double salts, $KFe^{III}(CrO_4)_2 \cdot 2\,H_2O$ [*20161-12-0*] and $NH_4Fe^{III}(CrO_4)_2 \cdot 2\,H_2O$ [*20161-14-2*] do exist, and potassium iron(III) chromate is a corrosion inhibitor. A similar corrosion-inhibiting compound is also thought to be formed on steel surfaces that are treated with chromate solutions. Industrially, the compound is produced by the reaction of iron(III) chloride solution with potassium dichromate in an autoclave at 130–160 °C. The precipitate is filtered and dried.

Lead chromate [*7758-97-6*], $PbCrO_4$, M_r 323.18, *mp* 844 °C (with evolution of oxygen), ϱ 6.123 g/cm^3, ΔH^0_{298} −910 kJ/mol, is a yellowish orange powder which occurs in three modifications:

$$\underset{\textit{yellowish orange}}{\text{monoclinic}} \xrightarrow{707\,^\circ\text{C}} \underset{\textit{yellow}}{\text{orthorhombic}} \xrightarrow{783\,^\circ\text{C}} \underset{\textit{red}}{\text{tetragonal}}$$

The solubility product in water is 1.5×10^{-14} at 18 °C. Lead chromate forms mixed crystals with lead(II) oxide, lead sulfate, and lead molybdate. All these salts are virtually insoluble in water; the molybdenum-containing compound is particularly well-known as molybdenum red. Lead chromate is prepared in a manner similar to that used for barium chromate. The composition, color, and quality of lead chromates depend on the conditions of precipitation; they are used widely as yellow to red pigments in the lacquer and paint industry (→ Pigments, Inorganic).

Silver Chromate and Silver Dichromate. Ag_2CrO_4 [*7784-01-2*], M_r 331.73, ϱ 5.625 g/cm^3, ΔH°_{298} −711.7 kJ/mol, S°_{298} 216 J mol^{-1} K^{-1}, c_p 142.3 J mol^{-1} K^{-1} (for solubility, see Table 8), and $Ag_2Cr_2O_7$ [*7784-02-3*], M_r 431.73, ϱ 4.770 g/cm^3, ΔH°_{298} −1218 kJ/mol, form dark red crystals and are soluble in acids, ammonia, and potassium cyanide solutions but not in water. The salts can be precipitated from a silver salt solution with chromate or dichromate solution and are used in the photographic industry.

Zinc chromate [*13530-65-9*], $ZnCrO_4$, M_r 181.36, is sparingly soluble in water but dissolves readily in acids. A series of zinc chromate hydrates exists having the composition $n\,ZnO \cdot m\,CrO_3 \cdot x\,H_2O$. In industry zinc chromate is known as zinc yellow. Its color may be controlled by the mode of preparation. It is made by the reaction of either a suspension of finely ground zinc white (ZnO) in concentrated sulfuric acid or water-soluble zinc salts ($ZnCl_2$, $ZnSO_4$) with potassium or ammonium dichromate. The zinc chromates prepared in this manner always incorporate potassium or ammonium ions into their lattice. Zinc chromate is used in lacquer primers as a corrosion inhibitor instead of minium (red lead) because of its ability to

form insoluble iron(III) chromates with iron or to passivate metal surfaces by oxidation.

7. Other Chromium Compounds

Chromyl chloride [*14977-61-8*], CrO_2Cl_2, M_r 154.90, *mp* − 96.5 °C, *bp* 116.7 °C, ϱ 1.912 g/cm^3, is a blood red oily liquid with a pungent smell, c_p 545 J kg^{-1} K^{-1}, ΔH°_{298} − 567.8 kJ/mol, S^0_{298} 510 J kg^{-1} K^{-1}, heat of fusion 268 kJ/kg. In the temperature range 178 – 390 K the vapor pressure obeys the equation

$$\log p = -3340T^{-1} - 9.08 \log T + 35.06$$

where p is in hPa (mbar) and T in K. The liquid is electrically conducting. Chromyl chloride is easily hydrolyzed; it is an extremely powerful oxidizing and chlorinating agent and, therefore, reacts with organic solvents, often violently. It decomposes in daylight within a week via CrO_2 and Cl_2 to form a series of chromium oxides and chlorides with a low degree of oxidation.

Industrially chromyl chloride is produced from chromium(VI) oxide and hydrogen chloride gas, with concentrated sulfuric acid (> 68 %) being used primarily to bind the water of reaction. The higher density chromyl chloride is drained, distilled, and collected in cooled receptacles.

Chromyl chloride can also be prepared by using mixtures or molten baths of sodium chloride and alkali chromates or dichromates with fuming sulfuric acid. An elegant route involves the reaction of chromium(VI) oxide with liquid thionyl chloride; these reactants are converted quantitatively into chromyl chloride by elimination of SO_2.

Hexacarbonylchromium [*13007-92-6*], chromium hexacarbonyl, $Cr(CO)_6$, M_r 220.06, ϱ 1.77 g/cm^3, forms colorless, highly refractive crystals which belong to the orthorhombic system. The compound sublimes slowly even at room temperature; when heated in a sealed tube it melts at 149 – 150 °C. The boiling point has been calculated to be 147 °C. At 210 °C, explosive decomposition occurs. The enthalpy of formation is − 1077 kJ/mol. Hexacarbonylchromium is somewhat soluble in chloroform and carbon tetrachloride but insoluble in benzene, ether, alcohol, and acetic acid. It is resistant to water and dilute acids at room temperature; there is no sign of attack even by concentrated hydrochloric acid or sulfuric acid in the cold, but concentrated nitric acid causes decomposition. No reaction with alkali occurs, but derivatives are produced with ammonia, pyridine, cyclopentadiene, and other organic ligands.

Attempts to synthesize hexacarbonylchromium directly from chromium and carbon monoxide have been unsuccessful. The action of carbon monoxide and a solution of phenylmagnesium bromide in ether on anhydrous chromium(III) chloride suspended in a mixture of benzene and ether produces intermediates that lead to hexacarbonylchromium upon addition of acid and distilling the ether in vacuo. Finely divided sodium can also be used for reduction instead of phenylmagnesium bromide. Yields of up to 80 % are reported when very finely divided sodium reacts with anhydrous chromium(III) chloride below 0 °C with carbon monoxide at a pressure of about 6 MPa (60 bar); the reaction proceeds in the presence of diethylene glycol dimethyl ether; the mixture is subsequently hydrolyzed while the carbon monoxide pressure is maintained [75].

Applications quoted for hexacarbonylchromium include the tempering and hardening of metal surfaces by chromizing, use as a fuel additive, an intermediate in the preparation of organic chromium compounds, and a catalyst for oxo syntheses.

Chromium(II) Compounds. In general, compounds of divalent chromium are extremely unstable in air and, therefore, are of only minor importance in industry. Gaseous chromium(II) halides (for preparation, see [76]) are used to produce chromium diffusion layers on iron and nickel parts. Air stable sodium fluorochromate(II) is said to be suitable for the precipitation of metals in electroplating operations and for corrosion-protection coatings [77].

8. Analysis

Compounds that are insoluble in water and acids, for example, chromium ore, are solubilized by roasting with sodium peroxide [78] in

the presence of soda. Chrome-tanned leathers are incinerated before being treated with sodium peroxide. Under these conditions, chromium is completely converted into water-soluble chromate(VI). The roasted mass is leached with hot water and after cooling sulfuric acid is added. Compounds of lower oxidation state that are soluble in water or acids are oxidized with ammonium persulfate to chromate(VI) in dilute boiling sulfuric acid in the presence of silver ions as catalysts [79]. Chloride ions must be removed beforehand. Traces of chloride ions are precipitated by adding a few drops of silver nitrate solution. The chromate(VI) solutions obtained in this way or solutions of chromium (VI) compounds that are soluble in water or sulfuric acid, are then titrated with iron(II) sulfate solution after phosphoric acid is added [80]. The end point of this titration can be determined potentiometrically or by means of a redox indicator, e.g., sodium diphenylamine-4-sulfonate [*6152-67-6*], [80]. Iodometric titration of chromate(VI) is also possible [81]. For very low concentrations, e.g., in the analysis of water, atomic absorption spectrometry (AAS) and inductively coupled plasma atomic emission spectrometry (ICP-AES) have proved successful [83]. Trace amounts of chromium are also detected photometrically at 540 nm after oxidation to chromate(VI) and addition of diphenylcarbazide [*140-22-7*] (formation of a reddish violet complex) [82].

9. Transportation, Storage, and Handling

Both hexavalent and trivalent chromium compounds are of commercial significance. Whereas the trivalent compounds and chromium(IV) oxide are not subject to regulations governing transport, the hexavalent compounds are classified internationally as dangerous goods. According to the IMDG code [85], the following classifications are applicable for hexavalent chromium compounds:

Compound	Hazard class	UN No.
$Na_2Cr_2O_7 \cdot 2\,H_2O$, crystals	6.1	3288
$Na_2Cr_2O_7$ solution	6.1	3287
$Na_2Cr_2O_7$ anhydr., crystals	5.1	3087
$K_2Cr_2O_7 \cdot 2\,H_2O$, crystals	6.1	3288
$(NH_4)_2Cr_2O_7$	5.1	1439
CrO_3, solid chromic acid	5.1	1463
Chromic acid solution	8	1755

During handling and storage, chromates, dichromates, and chromic acid must not be brought into contact with readily oxidizable substances.

A limit of 50 µg/L of chromium recommended by the WHO has been adopted in drinking water regulations. This figure was estimated by the U.S. Public Health Services from toxicity data. The value considers the No Observable Adverse Effect Level (NOAEL) from animal tests and the calculated Average Daily Intake (ADI) of drinking water consumers [86].

10. Environmental Protection

Wastewater. In Germany limits for the chromium content of wastewaters have been set up. The permitted concentrations depend on the type of industry. For the leather tanning industry, for instance, the concentration of Cr(IV) must not exceed 0.5 mg/L, and that of total chromium, 1 mg/L [87].

To avoid the pollution of water supply facilities, the risk of a release to surface and ground water has to be minimized during transportation, storage, and handling. In Germany, soluble hexavalent chromium compounds are classified in the highest water pollution class [88].

Exhaust Gas. In Germany, the emission of such carcinogenic chromates as calcium chromate, strontium chromate, chromium(III) chromate, and zinc chromate is limited to 1 mg/m^3 max. (as Cr) [89]; the emission of the other chromium compounds is limited to 5 mg/m^3 (as Cr).

Waste. Within the European Community, waste containing Cr(VI) compounds is considered hazardous [90]. It can only be deposited in dumps with particular safety measures and drainage-water treatment.

In Germany, sewage sludge containing not more than 900 mg per kilogram of chromium may be used as fertilizers in soils for agricultural purposes provided the chromium content of the soil does not exceed 100 mg chromium per kilogram soil before the application [91]. According to the U.S. Environmental Protection Agency, the chromium content of the soil should

not be regarded as a limiting factor for the application of sewage sludge [92]. Studies carried out in Germany on the use of sewage sludge containing a few percent of chromium(III) hydroxide as fertilizer did not reveal any adverse effects on soil and plants [93].

11. Ecotoxicology

Insoluble inert chromium(III) oxide, Cr_2O_3, is the stable mineral end product into which chromium compounds are converted in the environment as a result of natural processes.

Inland Waters. The natural concentration of dissolved trivalent chromium in surface waters is $< 1 - 10\,\mu g/L$ [94–96]. Hexavalent chromium does not occur in natural fresh waters. If dissolved trivalent chromium from anthropogenic sources enters an inland body of water, it precipitates under neutral conditions as chromium hydroxide. This ages and becomes increasingly insoluble, and only a small proportion remains in solution. Chromium(VI) compounds entering inland waters are reduced to chromium(III) compounds by the natural content of organic substances in water and sediments [97], [98].

Table 9 summarizes toxicity data for chromium(III) and chromium(VI) compounds in relation to fish, bacteria, algae, daphnia, and plants.

Limits for Chromium in Fresh Water. Various countries have set guidelines for the content of chromium in fresh water which can be considered tolerable [113–115]. Whereas the U.S. recommendations distinguish between trivalent and hexavalent chromium, both the Canadian and English guidelines consider total chromium.

Soil. The chromium content of the earth's crust varies from a few mg/kg to ca. 50 % in chromite deposits. The average chromium content of rock is 83 mg/kg. The chromium content of soil varies very widely, depending on the geological conditions. The range is from 5 to 1500 mg/kg, and the average concentration about 50 mg/kg [116]. The highest chromium contents are found in soils over basaltic rock. Chromium in soils is linked to the relicts of primary minerals such as chromite or olivine or bound by adsorption to clay minerals. Chromium is found everywhere in the soil of Germany [117], and levels of over 1100 mg/kg may be reached. Such levels are caused solely by geological conditions. All natural chromium is trivalent. Minerals of hexavalent chromium (eg. Crokoite) are extremely rare and can be found only in very few places worldwide.

Plants. As chromium occurs in soil only in the form of sparingly soluble chromium(III) compounds, which are available to plants only to a small extent, chromium is not enriched in the food chain [104], [105], [118–120].

Animals. Grazing animals are not subjected unduly to chromium since only small amounts enter the parts of plants above the ground [105]. Less than 1 % of the chromium contained in plants is available to animal and human organisms. To cover essential needs, the chromium must be in a special, biologically suitable form [121].

12. Nutrition

Chromium is an essential trace element both for the animal and human organism. A number of physiological functions in animal and humans can no longer proceed normally in a state of chromium deficiency [122], [123]. Examples include the role of chromium in glucose-tolerance factor, a cofactor for the action of insulin [124], in cytochrome C reductase [125], and in other metabolic processes [126].

The chromium content in food is in the range of 0.01 – 10 mg Cr/kg dry substance. Consumers in the western world ingest an average of 60 µg Cr per day in their food. The U.S. Food and Nutrition Board (1980) recommends [120] as the safe, but also adequate amount (average dietary intake): 50 to 200 µg per day.

The amount of chromium necessary to humans is not always guaranteed in the dietary intake and even with additional uptake from the environment. Therefore, nutrition science literature contains more references to deficiencies in chromium supply than any toxic effects due to chronic excess supply of chromium [127], [128].

Table 9. Ecotoxicology of chromium compounds

Species or medium	Chromium(III) compounds	Chromium(VI) compounds
Freshwater fish	**$CrCl_3$:** LC_{50} (48 h) minnows, static, 400 mg/L LC_{50} (48 h) trout, static, >1000 mg/L [99] LC_{50} (48 h) ides, static, 300 mg/L **$Cr_2(OH)_2(SO_4) \cdot Na_2SO_4$** LC_0 (30 days) *Brachydanio rerio*, static >1000 mg/L [100], [101]	**$K_2Cr_2O_7$:** 14 day no observable effect level (NOEL) for zebra fish (*Brachydanio rerio*) at 50 mg/L [107] or 80 mg/L [108]
Bacteria	**$KCr(SO_4)_2 \cdot 12\,H_2O$:** 100 mg/L proved not to be poisonous for bacteria of the genus *Escherichia* [100], [101]	**$Na_2Cr_2O_7 \cdot 2\,H_2O$:** toxic limiting concentration for *Pseudomonas putida* 0.78 mg/L [109]
Algae	**$KCr(SO_4)_2 \cdot 12\,H_2O$:** incipient injurious effect at 4 – 6 mg/L (*Scenedesmus*) [100]	**$K_2Cr_2O_7$** (*Scenedesmus subspicatus*): EC_{10} (96 h) 0.5 mg/L [107]; 0.3 – 1.3 mg/L [110]; 1.8 mg/L [108] EC_{50} (96 h) 1.4 mg/L [107]; 1.6 – 4.7 mg/L [110]
Daphnia	**$KCr(SO_4)_2 \cdot 12\,H_2O$** marked injurious effect at 42 mg/L [100]	**$K_2Cr_2O_7$** (21-day test): concentrations of > 0.1 mg/L markedly b decreased the production of offspring [108]; swimming ability of *Daphnia magna:* EC_0 = 0.3 mg/L; EC_{50} = 0.9 mg/L; EC_{100} = 2.2 mg/L [111]
Mammals (oral, rat)	**$Cr(NO_3)_3$:** LD_{50} 3250 mg/kg [102]	**$Na_2Cr_2O_7 \cdot 2\,H_2O$**: LD_{50} 160 mg/kg [112]
Soil mobility	**$Cr(NO_3)_3$:** low, only certain complex compounds are biologically available [103]	**$K_2Cr_2O_7$:** low since chromate is strongly adsorbed on the podsol type of soil and is also reduced by organic soil constituents [108]
Bioaccumulation	**$Cr(NO)_3$:** plants, particularly the parts above ground, do not absorb much chromium; accumulation of Cr is prevented at the very beginning of the food chain [104], [105]	**$K_2Cr_2O_7$:** carp (*Cyprinus carpio*): no bioaccumulation detected [108]
Higher plants **EC_{50} * (14 d)**	**$CrCl_3 \cdot 6\,H_2O$:** *Avena sativa* (oat) 560 mg of Cr/kg of soil [106] *Brassica rapa* (turnip) 230 mg of Cr/kg of soil [106]	**$K_2Cr_2O_7$**: oat: 27 mg/kg [107]; 32 mg/kg [108]; 96 mg/kg [110] turnip: 23 mg/kg [107]; 22 mg/kg [108]; 24 mg/kg [110]
Earthworm **LC_{50} (28 d)**	**$CrCl_3 \cdot 6\,H_2O$:** not known	**$K_2Cr_2O_7$:** > 2000 mg/kg of soil [107] no lethal effects at 1000 mg/kg [110]

* EC = effective concentration; at EC_{50} growth is retarded by 50 % compared with control.

For chromium the gap between essential and toxic concentrations is particularly large. Mammals can tolerate 100 to 200 times the normal chromium content of their bodies without adverse effects [129].

13. Toxicology and Occupational Health

The properties of chromium and its compounds which determine the toxicity and the impact on the environment differ greatly depending on the valency state. Only hexavalent chromium compounds are biologically active. Metallic chromium and the trivalent compounds, including those in chromium ores, are neither irritating, mutagenic, nor carcinogenic [129].

Reviews of the toxicity of chromium and its compounds are given in [130–132].

Chromium Dioxide. In a single administration, chromium dioxide is resorptively nontoxic; the lethal dose is greater than 17000 mg/kg (rats, oral). In rabbits, chromium dioxide causes slight

primary irritation of skin and mucous membranes.

Since any chromium dioxide in the normal atmosphere may contain traces of hexavalent chromium, care is to be taken during production and further processing to ensure that the concentration of chromium(VI) compounds at the workplace does not exceed the TLV for chromium(VI).

Employees of chromium dioxide plants are examined annually for chromium exposure. So far no indications have been found of any disease caused by chromium in chromium dioxide production plants.

Table 11. Estimated consumption of chromium ore in terms of products in 1984 [134], [137]

Product	World	United States
Ferrochromium, FeSi chromium, chromium metal, and foundry sands	72 %	60 %
Refractory bricks	12 %	20 %
Chemicals	17 %	20 %

Hexavalent Chromium Compounds. Particularly chromic acid and the alkali chromates corrode and irritate the skin and mucous membranes.

Acute Effects. Sodium monochromate and dichromate, potassium dichromate, and ammonium dichromate are soluble chromium(VI) compounds. These substances are toxic when swallowed, very toxic when inhaled, and dangerous to health when they come into contact with the skin. In humans, inhalation of these compounds, even at low doses, leads to coughing, chest pain, difficult breathing and fever.

Sodium monochromate and dichromate, potassium dichromate, and ammonium dichromate irritate the skin, eyes and respiratory tract. The risk of serious eye damage cannot be ruled out. In humans, repeated contact of hexavalent chromium compounds with the skin may lead to so-called chromium ulcers, but only on previously damaged parts of the skin.

Potassium dichromate and sodium monochromate show a skin-sensitizing effect in animal studies. There is evidence that soluble chromium(VI) compounds have a skin-sensitizing effect in humans. Skin allergy in humans is generally tested with potassium dichromate.

Hexavalent chromium compounds are capable of sensitizing the skin strongly, which may lead to chronic eczemas, particularly when the source is cement dust containing chromium(VI). In contrast, no sensitization of the respiratory tract occurs.

Uptake by the digestive system (mostly suicidal cases) causes serious intestinal inflammation, sometimes with loss of blood. Damage to the renal tubules occurs mainly after dermal absorption. This can lead to kidney failure if the spontaneous reduction capacity of plasma of about 2 ppm (20 min) is not sufficient to reduce chromium(VI) to nontoxic chromium(III). The

administration of high doses of ascorbic acid facilitates this reduction, and chromium(III) is then excreted in the urine without causing kidney damage [140].

Chronic Effects. Repeated inhalation of ammonium dichromate and sodium dichromate primarily affects the respiratory tract, while no corresponding studies are available with sodium monochromate and potassium dichromate. There are no significant data on repeated oral intake of ammonium dichromate or sodium dichromate, while liver and kidney damage have been described for sodium monochromate and potassium dichromate. In humans, prolonged inhalation of the dust damages the nasal mucosa or even the nasal septum (septal perforation) [139].

Chronic irritation of the nasal mucous membrane can lead to its atrophy. Chronic bronchitis has been reported following long-term exposure to hexavalent chromium compounds, but this does not occur normally under today's manufacturing conditions [129]. Impairment of breathing has not been observed.

Mutagenicity. Sodium monochromate and dichromate and potassium dichromate show mutagenic activity in tests with bacteria, microorganisms, cell cultures, and in animal studies. Ammonium dichromate shows mutagenic activity in tests with bacteria.

All hexavalent chromium compounds are mutagenic, but trivalent chromium compounds do not have any mutagenic potential. In some cases, the hexavalent compounds must first be solubilized to show a mutagenic effect. This effect is counteracted by the reduction of chromium(VI) to chromium(III), for example, by adding body fluids or organ homogenates [141], [142].

Carcinogenicity. Many animal experiments have been carried out to test the carcinogenicity of chromium compounds. These include subcutaneous injection, inhalation, intratracheal instillation, and introduction of pellets into the bronchial tree [143–147].

Depending on solubility, chromium(VI) compounds show carcinogenic activity after long-term inhalation. For this reason, the MAK Commission classed them under Group III A2 (substances with carcinogenic potential in animal studies).

Chromium(VI) compounds have been classed by IARC under Group I (carcinogenic in humans) based on early epidemiological studies, although clear classification of the findings to the category of carcinogenic substances was not possible.

The EU has classified chromic acid and zinc chromates as category 1 carcinogens (human carcinogens), other chromates/dichromates ($SrCrO_4$, $CaCrO_4$, $Na_2Cr_2O_7$, $K_2Cr_2O_7$, K_2CrO_4) as category 2 carcinogens (animal carcinogens), and PbCrO4 as category 3 carcinogen (suspected carcinogens) [148].

In the United States [149], water-soluble Cr(VI) compounds and insoluble Cr(VI) compound – both "not otherwise classified" – are considered A1, i.e., "confirmed humans carcinogens"

Reproductive Toxicity. In animal studies, sodium dichromate and potassium dichromate do not induce deformities at nonmaternotoxic doses. An embryotoxic effect has been described for potassium dichromate. There are no data on an embryotoxic effect of ammonium dichromate or sodium monochromate.

In animal studies, inhalation of sodium dichromate does not impair fertility. Animal studies with potassium dichromate and sodium monochromate at doses that are nontoxic to the animals yield no evidence of a fertility-impairing effect. There are no data on a fertility-impairing effect of ammonium dichromate.

Epidemiology. Epidemiological studies among workers in chrome-tanning plants and chrome(III) pigment manufacturing plants have proved trivalent chromium compounds to be noncarcinogenic [150].

Earliest indications of increased incidences of lung cancer among workers in the chromate manufacturing industry were observed in the 1930s. More evidence in support of this observation came from a large number of epidemiological studies carried out after 1948 [151], [152]. Studies carried out between 1948 and 1956 showed a 25- to 29-fold increase in the incidence of lung cancer. In contrast, investigations performed since 1979 reflect the effects of improved hygienic working conditions and production processes, for example, by avoiding the use of lime in the oxidative roasting of chromium ores (low-lime process). These measures have led to a convergence between the incidences of

Table 12. Imports of chromium ore∗ into the Federal Republic of Germany [138]

	1981	1982	1983
1000 t	268	244	247
Millions of €	25.0	22.4	21.6
Price, €/t	93.00	91.57	87.58

∗ Includes all types of chromium ore.

lung cancer observed in the workers and that expected in unexposed persons [139], [153–156].

An increased incidence of lung cancer was observed among persons employed in the chromate pigment industry only after exposure to zinc chromate. Lead chromate showed no carcinogenic effect [157–159]. Results of epidemiological studies carried out during the handling of chromic acid, particularly during chromium plating, are blurred by confounding factors; a statistically significant increase in the rate of lung cancer was not observed [143], [160]. An increased risk of lung cancer has also not been clearly established in the manufacture of ferrochromium [161], [162]. Occupational health care has been provided in the chromate-producing industry for several decades.

Classification. According to the EU List of Dangerous Substances [148] the following labelling has to be applied for

Occupational Exposure Limits.

Germany [163]. The TRK values for Cr(IV) compounds, except those which are practically insoluble in water, are (as CrO_3in total dust) for

Arc welding	0.1 mg/m^3 (corresponding to 0.05 mg/m^3 as Cr)
Manufacturing of soluble Cr(IV) compounds	0.1 mg/m^3 (0.05 as Cr)
Others	0.05 mg/m^3 (0.025 as Cr)

United States [149]. The TLV values (as Cr) are as follows;

Cr metal and Cr(III) compounds	0.5 mg/m^3
Water-soluble Cr(IV) compounds	0.05 mg/m^3
Insoluble Cr(IV) compounds	0.01 mg/m^3

Biological Monitoring. In addition to the classical assay for chromium in blood or urine, the degree of previous exposure to chromium can be estimated by determining the extent of bound chromium in erythrocytes [164].

14. Economic Aspects

The output of chromium ore is subject to considerable variations. Rich ores which are obtained easily by handpicking have declined. This shrinkage in output has to be counterbalanced by exploiting low-grade ores and upgrading them to saleable concentrates. The statistical documents are incomplete and contradictory. Table 10 shows the output of chromium ores according to various sources of information.

Even the most pessimistic estimates of the worldwide reserves and the extraction possibilities in individual countries do not predict a chromium shortage before the end of this century. In addition, the huge lean-ore deposits in South Africa, Southeast Asia, and the United States, which are still completely untouched, afford a replacement for the rich ores being mined at present.

In Table 11 the consumption of chromium ore is broken down according to products. The refractory brick share is declining because Siemens – Martin steel is being increasingly supplanted by oxygen-blown steel produced in converters with a basic lining.

Table 12 shows chromium ore imports into the Federal Republic of Germany and Table 13 the share of individual applications in the consumption of chromium chemicals.

Table 13. Estimated share (in %) of individual applications in the consumption of chromium chemicals, 1985∗

1. Introduction

Cinnamic acid [*621-82-9*], 3-phenylpropenoic acid, $C_9H_8O_2$ M_r 148.16, exists in cis and trans forms.

The more stable isomer is the trans isomer, which occurs naturally and is the usual commercial product.

Cinnamic acid was first isolated as crystals from cinnamon oil by TROMMSDORF in 1780. He thought it was benzoic acid. DUMAS and PÉLIGOT identified it in 1835, and in 1856 BERTAGNINI succeeded in synthesizing it from benzaldehyde and acetyl chloride.

2. Physical Properties

trans-Cinnamic acid [*140-10-3*] forms colorless crystals with a faint balsamic odor, *mp* 133 °C, *bp* 300 °C (101.3 kPa) and 173 °C (13.3 kPa), d_4^4 1.2475, d_4^{180} 1.0270. The heat of combustion is 30.5 kJ/g. *trans*-Cinnamic acid is only slightly soluble in water, but it is highly soluble in polar organic solvents.

cis-Cinnamic acid [*102-94-3*] exists in three crystalline forms: *cis*-allocinnamic acid, *mp* 68 °C, and two *cis*-isocinnamic acids, *mp* 58 °C and 42 °C. The lower melting *cis*-isocinnamic acid is extremely unstable and isomerizes spontaneously to *cis*-allocinnamic acid. The three *cis*-cinnamic acids can be interconverted, e.g., by inoculating their melts.

3. Chemical Properties

Cinnamic acid undergoes reactions typical of a carboxyl group and an olefinic double bond. The carboxyl group can be esterified to form cinnamates, some of which are important flavorings and fragrances. When reacted with inorganic acid chlorides, such as thionyl chloride or phosphorus chlorides, cinnamic acid gives cinnamoyl chloride [*102-92-1*]. When heated, cinnamic acid forms styrene [*100-42-5*] and carbon dioxide. With oxidizing agents or when heated with alkali, the olefinic double bond cleaves to give benzaldehyde [*98-87-3*].

Hydrogenation of cinnamic acid leads to 3-phenylpropionic acid [*501-52-0*] or 3-cyclohexylpropionic acid [*701-97-3*], depending on the reaction conditions. The addition of bromine to the olefinic double bond of cinnamic acid forms 2,3-dibromo-3-phenylpropionic acid [*6286-30-2*], an intermediate in the manufacture of the fragrant substance β-bromostyrene [*103-64-0*]. Hydrohalogenation gives 2-halo–3-phenylpropionic acids. Dimers, such as truxinic acid (3,4-diphenyl-1,2-cyclobutanedicarboxylic acid) [*4482-52-4*] and α-truxillic acid (2,4-diphenyl-1,3-cyclobutanedicarboxylic acid) [*490-20-0*], are formed from cinnamic acid under the influence of sunlight. Cinnamic acids with substituents on the benzene ring are seldom prepared by direct substitution reactions of cinnamic acid.

4. Occurrence in Nature

Cinnamic acid, usually the trans isomer, occurs naturally in the free state and as an ester, e.g., in essential oils. Cinnamic acid is a constituent of cassia oil, of the extract oil from *Populus balsamifera,* and of the essential oils from leaves and peels of *Citrus bigaradia*. Cinnamates, especially methyl- [*1754-62-7*], benzyl- [*103-41-3*], cinnamyl- [*122-69-0*], and hydrocinnamyl cinnamates [*122-68-9*], are found in numerous essential and balsam oils (methyl cinnamate in oils of the *Alpinia* species and varieties of *Ocimum canum;* benzyl, cinnamyl, and hydrocinnamyl cinnamates in Peru, Tolu, and storax balsam oils). Siam and Sumatra benzoin [*9000-73-1*] resins also contain cinnamates.

5. Production

Commercial synthesis of cinnamic acid almost always results in the trans isomer.

5.1. Perkin Reaction

The Perkin reaction is the oldest known method of producing cinnamic acid commercially. In this reaction benzaldehyde [*100-52-7*] is condensed with acetic anhydride in the presence of sodium acetate as catalyst.

Other possible catalysts are potassium acetate, tertiary amines, potassium phosphate [2] and trimethyl borate [3].

5.2. Claisen Condensation

The Claisen condensation of benzaldehyde with acetic acid esters in the presence of alkali alcoholates yields cinnamic acid esters, which can be saponified to form cinnamic acid.

where R^1 and R^2 may be the same or different alkyl groups

5.3. Benzal Chloride Reaction

Benzal chloride [*98-87-3*] reacts with alkali acetate in an alkaline medium to give a high yield of cinnamic acid. Cinnamic acid can be obtained by this reaction in the presence of amines such as pyridine in more than 80 % yield [4].

5.4. Oxidation of Cinnamaldehyde

Cinnamaldehyde [*104-55-2*] can be oxidized to cinnamic acid by using oxygen and a catalyst, e.g., silver [5] or palladium on charcoal [6].

5.5. Preparation of Cinnamic Acid Esters

Cinnamic acid esters can be prepared from styrene, alcohols, carbon monoxide, and oxygen by using catalysts such as platinum [7] or palladium [8].

6. Uses

Cinnamic acid is an important intermediate in the preparation of its esters, which are used

as fragrances, for pharmaceuticals, and for the enzymatic production of L-phenylalanine, the starting material for peptide sweeteners. Sodium cinnamate is a known corrosion inhibitor. Cinnamic acid is also used as a brightener in cyanide-free zinc electroplating baths [9], a corrosion inhibitor during removal of scale from zinc [10] and in aerosol cans [11], a low-toxicity heat stabilizer for poly(vinyl chloride) [12], a cross-linking agent for dimethyl terephthalate – ethylene glycol copolymer [13] and polyurethanes [14], a fireproofing agent for polycaprolactam [15], in laundry-resistant polyurethane adhesives for polyester fibers [16], and for improvement of the storage stability of drying-oil-modified alkyd resin coatings [17].

7. Quality Specifications

Cinnamic acid used in fragrances and foods must be 99 % pure after drying. The melting point should be 133 °C, and the chlorine content not more than 0.005 wt % [18].

8. Economic Aspects

The annual worldwide production of cinnamic acid has increased to several thousand tons due to the steadily increasing demand for artificial dipeptide sweeteners (→ Sweeteners). Bayer (Federal Republic of Germany), DSM (the Netherlands), and Kay Fries (United States) are among the major producers.

9. Toxicology

The acute oral LD_{50} in rats is 2.5 g/kg, and the acute dermal LD_{50} in rabbits exceeds 5 g/kg. Cinnamic acid applied neat to intact or abraded rabbit skin for 24 h was slightly irritating; a 4 % solution in petrolatum produced no sensitization in man [19].

1. Introduction

Citric acid [*77-92-9*], $C_6H_8O_7$, M_r 192.13, is a tricarboxylic acid. According to IUPAC-nomenclature, citric acid is 2-hydroxypropane-1,2,3-tricarboxylic acid; it is also known as β-hydroxytricarballylic acid.

Citric acid was isolated and crystallized in 1784 by SCHEELE, who precipitated calcium citrate by adding lime to lemon juice. The presence of three carboxyl and one hydroxyl groups was recognized by LIEBIG in 1838. Citric acid was first prepared from calcium citrate in 1860 in the United Kingdom. By 1880 citric acid was being produced from calcium citrate in France, Germany, and the United States.

Citrus fruits contain citric acid in large quantities, from 5 % in the fruit [1] to 9 % in the juice [2]. Citric acid is also found in many other fruits. The citric acid content (in mg/100 mL) of various common fruits is as follows [3], [4]:

Lime	7000
Lemon	5630
Raspberry	2480
Black currant	1170
Tomato	1018
Pineapple	605
Strawberry	580
Cranberry	202
Apple	14

In addition to fruits citric acid is found in almost all plant and animal species. The *citric acid cycle,* also known as the Krebs cycle or tricarboxylic acid cycle (see Fig. 1), is pivotal in the oxidation of sugars and acetates to carbon dioxide and water, releasing energy for physiological functions [5], [6].

Figure 1. Citric acid cycle of plants and animals [5], [6]

About 100 years after citric acid had been isolated from citrus fruits, it was synthesized from glycerol. The finding, in 1893, that certain microorganisms secrete citric acid when grown on sugar media suggested the possibility of producing the acid commercially by fermentation. The first successful operation of this type began 1923 in New York; later large-scale fermentation processes were developed in the former Czechoslovakia, the United Kingdom, Belgium, and Germany. Submerged fermentation has been used since the middle of this century.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a07_103

Citric acid fermentation, whether surface or submerged, used carbohydrate substrates with certain strains of the mold *Aspergillus niger*. Since the early 1970s, other microorganisms have been introduced, including molds, yeasts, and bacteria, and other substrates, e.g., various carbohydrates and n-alkanes from crude oil.

2. Physical Properties

Citric acid is a colorless, odorless substance with an agreeable, though strongly acid taste. The monohydrate crystallizes from a saturated solution below 36.6 °C and the anhydrous form at higher temperature. The *monohydrate*, M_r 210.13, has a relative density of 1.542 and a heat of combustion at 30 °C of 1973 kJ/mol; it softens at 75 °C and melts at 100 °C. Its translucent, colorless crystals belong to the orthorhombic system. *Anhydrous citric acid, mp* 153 °C, has a relative density of 1.665 and a heat of combustion at 30 °C of 1990 kJ/mol. The crystals are translucent and colorless, belonging to the holohedral class of the monoclinic system. Both forms exist under conditions of normal humidity; dehydration of the monohydrate occurs in very dry air and is more rapid when it is carried out under vacuum in the presence of concentrated sulfuric acid. The anhydrous crystals gradually absorb water in moist air; both crystalline forms clump and harden in moist air.

The solubility of citric acid in water as a function of temperature is shown in Figure 2; the temperature of the solution drops as the acid dissolves. The pH of citric acid solutions as a function of concentration is shown in Figure 3. The freezing point depression and boiling point elevation of citric acid solutions are given in Table 1. The dissociation constants at 18 °C are K_1 8.2×10^{-4}, K_2 1.8×10^{-5}, and K_3 4.0×10^{-6}.

3. Chemical Properties

Citric acid loses water at 175 °C to form aconitic acid, HOOCCH=C(COOH) (CH_2COOH), which loses carbon dioxide to yield itaconic anhydride [*2170-03-8*]. Itaconic anhydride rearranges to citraconic anhydride [*616-02-4*] or adds water to form itaconic acid [*97-65-4*], (HOOCCH_2) (HOOC)C=CH_2.

Addition of water to citraconic anhydride gives citraconic acid [*498-23-7*], *cis*-HOOCCH=C(CH_3) (COOH). Evaporation of a citraconicacid solution in the presence of nitric acid yields mesaconic acid [*498-24-8*], the trans isomer of citraconic acid.

Potassium permanganate oxidation of citric acid at 35 °C yields 1,3-acetonedicarboxylic acid [*542-05-2*], HOOCCH_2 $COCH_2$ COOH; at 85 °C the productis oxalic acid [*144-62-7*], HOOCCOOH. Fusion with potassiumhydroxide produces oxalic and acetic [*64-19-7*] acids.

Citric acid forms crystalline mono-, di-, and tribasic salts with manycations. The degree of hydration of these salts varies; thus, trisodium citrate can crystallize with 2 or 5.5 molecules of water. Mixtures of metal cations give complex salts, such as $ZnNa_3H(C_6H_5O_7)_2$, $ZnNa_4(C_6H_5O_7)_2$, and $Zn(Na_3C_6H_4O_7)_2$.

Citric acid forms stable complexes with many metals; some, such as ferroammonium citrates, can be crystallized. Copper gives a complex resembling the copper – tartaric acid complex of Fehling's solution. These complexes have been studied by various classical methods.

Citric acid can chelate many metal ions in solution by forming bonds between the metal and the carboxyl or hydroxyl groups of the citric acid molecule. Sometimes two or more citric acid molecules are involved in the interaction with the metal ion. This property is valuable for preventing precipitation (e.g., bathtub ring from soap), changing chemical potential, and altering other chemical properties.

Citric acid is easily esterified with many alcohols under the usual conditions in the presence of a catalyst, such as sulfuric acid, *p*-toluenesulfonic acid, or an acid ion-exchange resin; esterification with alcohols boiling above 150 °C requires no catalyst. Benzyl chloride and sodium citrate yield di- or tribenzyl esters. Trimethyl, triethyl, and tributyl citrate are used as plasticizers in food-packaging materials.

Dihydric alcohols, dihydric phenols, and polyhydric alcohols, such as mannitol, sorbitol, and glycerol, form polyesters with citric acid. In some cases the esterification reaction can be stopped before completion, leaving at least one of the carboxylic acid moieties free to form a salt; the resulting polyester may be soluble in water.

Acid chlorides and anhydrides react with the hydroxyl group of citric acid; usually the ester of citric acid is used and the allyl ester is formed. Dicarboxylic acid chlorides give bis(citric acid esters).

Epoxides, such as ethylene oxide, propylene oxide, and styrene oxide, form polymers by reacting with citric acid or its esters at the available hydroxyl and carboxyl groups.

Ammonia, amines, amides, and carbamides react with citric acid as they do with simple carboxylic acids. Aldehydes form adducts with citric acid; e.g., formaldehyde gives anhydromethylenecitric acid [*144-16-1*] 5-oxo-1,3-dioxolane-4,4-diaceticacid:

4. Production

4.1. Laboratory Synthesis

The classic laboratory synthesis of citric acid beginning with acetone has not been used on an industrial scale:

Reaction conditions at each stage are critical and use of bromine and hydrogen cyanide is hazardous. A simplified version of this synthesis has been patented [7].

Another synthesis is as follows:

The key step in this route is the catalytic condensation of ketene with oxalacetic anhydride, which can be obtained by catalytic oxidation of malic or fumaric acid.

Other syntheses are found in the patent and scientific literature, but apparently none have been commercialized [8], [9].

4.2. Early Production

For about 50 years, citric acid was obtained exclusively from unripe citrus fruit. In southern Italy, an entire industry with orchards and processing facilities was devoted to this purpose. The juice was pressed from unripe fruit and mixed with lime (CaO) to precipitate calcium citrate. The solid was treated with sulfuric acid to precipitate calcium sulfate and form a solution from which citric acid was crystallized. The yield of purified product was about 2 – 3 wt % of the fruit; citrus oils were also obtained. This procedure has been displaced by fermentation.

4.3. Fermentation

The most economical method for producing citric acid since the 1930s has been fermentation, which employs a strain of *Aspergillus niger* to convert sugar to citric acid. Both surface fermentation and submerged fermentation have been used.

4.3.1. Surface Fermentation

In surface fermentation, *A. niger* is grown on a liquid substrate in pans stacked vertically in a chamber. The chamber and pans are sterilized either before or after introduction of the substrate. The pans are filled manually or automatically. The chamber is warmed by the introduction of moist, sterile air at a controlled temperature. The liquid and the surface microorganisms are removed manually or automatically from the pans. The pans are cleaned before the next batch is introduced.

The substrate for the fermentation is a carbohydrate, usually molasses or a sugar, such as raw beet, refined beet, or cane sugars, or a syrup. Glucose syrups can be prepared from wheat, corn, potato, or other starch. The sugar content of the syrup can vary from about 10 to 25 wt %. Certain inorganic nutrients, such as ammonium nitrate, potassium phosphate, magnesium sulfate, zinc sulfate, and potassium ferrocyanide, are added. The pH is adjusted to between 3 and 7, depending on the carbohydrate source. Sterilization may be batchwise or continuous; the latter uses less energy and is usually faster. After sterilization, the temperature is adjusted as required.

The surface of the sterile substrate in the pans is inoculated with *A. niger* spores, which germinate and cover the surface of the liquid with a mat of mold. After two to three days the surface is completely covered and citric acid production begins, continuing at almost a constant rate until 80 – 90 % of the sugar is consumed. Fermentation then continues more slowly for an additional six to ten days.

The theoretical yield from 100 kg of sucrose is 123 kg of citric acid monohydrate or 112 kg of anhydrous acid. However, the *A. niger* uses some sugar for growth and respiration, and the actual yield varies between 57 and 77 % of theoretical, depending on such factors as substrate purity, the particular strain of organism, and the control of fermentation.

4.3.2. Submerged Fermentation

Submerged fermentation is similar to surface fermentation, but takes place in large fermentation tanks. This method is used more frequently because labor costs are lower with large tanks than with small pans; equipment costs are also lower.

The fermentation vessel can be short and wide or tall and narrow, and equipped with mixing devices, such as top-entering or side-entering agitators of the turbine or propeller type. Agitation can be increased by use of a draft tube, a recirculation loop, or a nozzle through which air and recirculated substrate is pumped. Spargers located at the bottom of the vessel or under the stirrer supply air, which may be enriched with oxygen. Oxygen is usually recovered from the exhaust gas. The air is supplied by a compressor and passes through a sterile filter; if necessary, the air is cooled. Because the process is exothermic, the vessel must be equipped with heat-exchange surfaces, which can be the outside walls or internal coils. Ports are provided for introducing substrate, inoculum, and steam or other sterilizing agents; sampling and exhaust ports are also provided.

The substrate is prepared in a separate tank and its pH adjusted; the micronutrients may be added to this tank or directly to the fermentor. The substrate is sterilized by a batchwise or, more commonly, by a continuous operation. The fermentor is sterilized, charged with substrate, and inoculated. Fermentation requires 3 – 14 days. After it is completed, the air supply is stopped to prevent the microorganisms from consuming the citric acid.

4.3.3. Other Fermentation Methods

Citric acid can also be produced from hydrocarbons using yeast. The process resembles submerged fermentation, but requires more air. It is a four-phase process, i.e., air, organic liquid, aqueous liquid, and solid, and some operational details are different.

4.4. Recovery

The citric acid broth from the surface or submerged fermentation processes must be purified. First, biological solids usually are removed by filtration using a rotary vacuum filter or the more recent belt-press filter, or by centrifugation. The solids are washed to improve recovery of citric acid.

The dissolved citric acid must then be separated from residual sugars, proteins generated by the fermentation, and other soluble impurities. This has traditionally been accomplished by precipitation and crystallization. Addition of lime precipitates calcium citrate, which is filtered and stirred in dilute sulfuric acid to form a precipitate of calcium sulfate; filtration yields a purified citric acid solution. Control of pH and temperature in these operations helps to optimize the results. Citric acid is then crystallized from solution and recrystallized from water; the mother liquors are recycled to remove accumulated impurities.

Other purification techniques can be used, including ion exchange, carbon adsorption, membrane filtration, chromatography, and liquid extraction.

After filtration or centrifugation, the citric acid crystals are dried, classified, and sold in bags or in bulk. Crystals of the wrong size are recycled. Citric acid is also sold as an aqueous solution of varying degrees of purity.

Byproducts of these purification processes include biomass from the primary filtration, which can be sold for feed, and calcium sulfate, which can be used for landfill or for industrial purposes, such as manufacture of gypsum board. Soluble organic impurities are given normal wastewater treatment.

Few changes in production methods have occurred in recent years, but research has been done on the fermentation process [10] and on new separation techniques [11].

5. Quality Specifications and Uses

Specifications. The Food Chemical Code specifications for citric acid are as follows [12]:

> *Description:* colorless, translucent crystals or white, granular to fine crystalline powder; odorless, strongly acid taste; hydrate is efflorescent in dry air

Solubility: 1 g of anhydrous acid dissolves in 0.5 mL of water, in 2 mL of alcohol, and in 30 mL of ether
Identification: 1-in-10 solution gives positive tests for citrate
Assay: not less than 99.5 % $C_6H_8O_7$, calculation based on the anhydrous form
Water: not more than 0.5 % (anhydrous form) and not more than 8.8 % (hydrate)
Limits of impurities: arsenic (as As): not more than 3 ppm (0.0003 %)
heavy metals (as Pb): not more than 10 ppm (0.001 %)
oxalate: passes test; no turbidity produced
readily carbonizable substances: passes test
residue on ignition: not more than 0.05 %

For specific test methods, see [12].

Uses. Citric acid and its sodium or potassium salts are used in many food products, including carbonated beverages, dry-packaged drinks, fruit drinks, jams, jellies, and canned fruits. They are also important in producing vegetable oils and in preserving the color, flavor, and vitamin content of fresh and frozen vegetables and fruit.

Citric acid is widely used in cleaning, e.g., for boilers and heat exchangers. Its chelating ability assists in removal of scale. Citric acid is employed as a detergent builder, especially in liquid formulations. Its solutions can remove sulfur dioxide from gases and chelate micronutrients in fertilizer. Citric acid esters are plasticizers for food-grade plastic containers.

6. Economic Aspects

Citric acid is manufactured worldwide. The United States and Western Europe are the major producers; however, capacity has recently increased in the Far East and in Eastern Europe. The location of new facilities depends on access to raw materials and markets.

7. Production and Consumption

Clays are important industrial minerals that are utilized around the world. The clay minerals and materials discussed here are kaolins, smectites, palygorskite and sepiolite, and miscellaneous or common clays. Kaolin is both a rock term and a group minerals name for kaolinite, dickite, nacrite, and halloysite. Bentonite is a rock term and the dominant minerals in bentonite are smectites, which is a group mineral name. Important minerals in the smectite group are sodium, calcium, magnesium, iron, and lithium montmorillonites. Miscellaneous or common clays include shales, mudstones, soil clays, lacustrine clays, glacial tills, and so on, which are used for making brick, tile, other structural clay products, and stoneware pottery. They are usually comprised of a mixture of clay and nonclay minerals, the most common of which are illite, chlorite, mixed-layer clays, and quartz. The geology and location of clay deposits that are marketed regionally and worldwide are described. Structure,

composition, and chemical and physical properties of the clay minerals are discussed. These control the many industrial applications of clay minerals and materials. Important applications are described. World production figures of the various clays are given as of 2004. A brief discussion on health-related and environmental issues is included.

[Top of Page]

1. Introduction

The term *clay* has a double meaning and, therefore, should be defined when it is used. Clay is used both as a rock term and as a particle size term. As a rock term, clay is used for a natural, earthy, fine-grained material composed largely of a limited group of crystalline minerals known as the clay minerals. As a particle size term, clay is used for the category that includes the smallest particles. Soil investigators and mineralogists generally use 2 μm as the maximum size, although the Wentworth scale [1] defines clay as material finer than 4 μm. GRIM [2] uses the term clay material for any fine-grained, natural, earthy, argillaceous material; in this way, the term can include clays, shales, or argillites, and some soils if they are argillaceous.

Clay is an abundant raw material and has an amazing variety of uses and properties that depend on the clay mineral composition and other factors enumerated by GRIM [2]. These factors are clay mineral composition, nonclay mineral composition, presence of organic material, the type and amount of exchangeable ions and soluble salts, and texture.

Clays are comprised of certain groups of hydrous aluminum, magnesium, and iron silicates that may contain sodium, calcium, potassium, and other ions. These silicates are called the clay minerals, and the major clay mineral groups are kaolins, smectites, illites, chlorites, and palygorskite and sepiolite. The specific clay minerals are identified by several techniques, including X-ray diffraction [3], differential thermal analysis [4], electron microscopy [5], and infrared spectrometry [6]. Identification and quantification of the clay minerals and nonclay minerals present in a clay material is important because the uses and engineering properties are controlled largely by these two factors.

Clays and clay minerals are important geologically, industrially, and agriculturally; they are important to the engineer in building foundations, tunnels, road cuts and fills, and dams. There are several scientific groups whose work is largely devoted to clays, including AIPEA (Association Internationale pour l'Étude des Argiles), Clay Minerals Group of the Mineralogical Society of Great Britain, CMS (Clay Minerals Society, United States), European Clay Minerals Society, Clay Minerals Society of Japan, and the Australian Clay Minerals Society. Major publications include the *Proceedings of International Clay Conferences*, published by AIPEA; *Clays and Clay Minerals*, published by CMS; *Clay Minerals*, published by the Mineralogical Society of Great Britain; *Clay Mineral Science*, published by the Clay Society of Japan; and *Applied Clay Science*, published by Elsevier.

2. Structure and Composition of Clay Minerals

GRIM [2] proposed a tentative classification based on the structural attributes of the various clay minerals. This classification is relatively simple:

- I. Amorphous
  - Allophane group [12172-71-3]
- II. Crystalline
  - A. Two-layer types (sheet structures composed of units of one layer of silica tetrahedrons and one layer of alumina octahedrons)
    - 1. Equidimensional
      - Kaolin group [1332-58-7]
        - kaolinite [1318-74-7],
        - dickite [1318-45-2],
        - nacrite [12279-65-1]
    - 2. Elongate
      - halloysite [12244-16-5]
- III. Three-layer types (sheet structures composed of two layers of silica tetrahedrons and one central dioctahedral or trioctahedral layer)
  - 1. Expanding lattice
    - Smectite group [12199-37-0]
    - a. Equidimensional
      - montmorillonite [1318-93-0],
      - sauconite [12424-32-7],
      - vermiculite [1318-00-9]
    - b. Elongate
      - nontronite [12174-06-0],
      - saponite [1319-41-1],
      - hectorite [12173-47-6]
  - 2. Nonexpanding lattice
    - Illite group [12173-60-3]
- IV. Regular mixed-layer types (ordered stacking of alternate layers of different types)
  - Chlorite group
- V. Chain-structure types (hornblende-like chains of silica tetrahedrons linked together by octahedral groups of oxygens and hydroxyls containing aluminum and magnesium ions)
  - palygorskite [12174-11-7]
  - (attapulgite [1337-76-4]),

sepolite [15501-74-3]

The materials described as *allophane* are amorphous [7] and contain variable proportions of silica, alumina, and water. Allophane is commonly associated with halloysite and generally has a glassy appearance.

The kaolin minerals [8] are hydrous aluminum silicates and have the approximate composition $2\ H_2O \cdot Al_2O_3 \cdot 2\ SiO_2$. *Kaolinite* is the most common of the kaolin minerals. The structure of kaolinite consists of a single silica tetrahedral sheet and a single alumina octahedral sheet combined to form the kaolin unit layer (Fig. 1). These unit layers are stacked on top of each other. Variations in orientation of the unit layers in stacking cause differences in the kaolin mineral itself and lead to the differentiation of *nacrite* and *dickite* in the kaolin group [2]. Platy and vermicular forms of kaolinite are shown in the electron micrograph in Figure 2.

Figure 1. Structure of kaolinite

○ Oxygen; ⊙ Hydroxyl; ○ Silicon tetrahedrally coordinated; ● Aluminum octahedrally coordinated

Figure 2. Scanning electron micrograph of kaolinite stacks and plates

Halloysite is an elongate mineral that occurs in a hydrated and dehydrated form [7]. BATES et al. [9] proposed that the hydrated form of halloysite consists of curved sheets of kaolin unit layers (Fig. 3), which is consistent with electron micrographs (Fig. 4).

Figure 3. Structure of halloysite

A) Dehydrated halloysite; B) Hydrated halloysite; C) Proposed curved structure of halloysite

Figure 4. Scanning electron micrograph of elongate halloysite (bar = 2 μm)

Smectite is composed of units consisting of two silica tetrahedral sheets with a central alumina octahedral sheet. The lattice has an unbalanced charge because of substitution of alumina for silica in the tetrahedral sheet and iron and magnesium for alumina in the octahedral sheet. Because of this and because oxygen layers are adjacent when these unit layers are stacked, the attraction holding these layers together is weak, and cations and polar molecules can enter between the layers and cause expansion (Fig. 5). Sodium *montmorillonite* is a smectite in which sodium and water molecules are the interlayer material, and calcium montmorillonite is a smectite in which calcium and water molecules are the interlayer material. Figure 6 shows an electron micrograph of a sodium montmorillonite.

Figure 5. Structure of smectite

○ Oxygen; ⊙ Hydroxyl; ● Aluminum, iron, magnesium; ○• Silicon, occasionally aluminum

Figure 6. Scanning electron micrograph of a sodium montmorillonite (Wyoming)

Sauconite is a smectite in which zinc has replaced some of the aluminum. *Nontronite* results when iron replaces the aluminum, and *saponite* results when magnesium replaces aluminum. *Hectorite* results when magnesium replaces aluminum and lithium is the ion between the layers.

Vermiculite is an equidimensional expandable clay mineral. The structure [10] consists of a layer made up of two silica tetrahedral sheets with a central magnesium – iron octahedral sheet separated by two layers of water molecules and adsorbed magnesium and calcium ions. Vermiculite differs from montmorillonite in that the layers do not expand as much and show less random stacking [2].

Illite is a general term for the micalike clay mineral [11]. The basic structural unit is a layer composed of two silica tetrahedral sheets and a central octahedral sheet. The unit is similar to that of montmorillonite except that more aluminum ions replace silicon in the tetrahedral sheet, which causes a charge deficiency. This charge deficiency is balanced by potassium ions that act as a bridge between the unit layers and bind them together so that illites are nonexpandable (Fig. 7).

Figure 7. Structure of illite

○ Potassium; ○ Oxygen; ● Aluminum (only 2/3 of available positions filled); ⊙ Hydroxyl; ○ Silicon (1/4 replaced by aluminum)

Another common group of clay minerals is the *chlorite* minerals. The structure consists of alternate mica layers and brucite layers (Fig. 8). The brucite-like layer can be a magnesium, aluminum, or iron hydroxide, or a combination of all three. The various members of the chlorite group are differentiated on the kind and amount of substitution in the brucite and the mica layers [12].

Figure 8. Structure of chlorite

○ Magnesium, iron (all available positions filled); ⊙ Hydroxyl; ○ Oxygen; ° Silicon (1/4 replaced by aluminum)

The clay minerals *palygorskite* (attapulgite) and *sepiolite* have a chainlike structure (Fig. 9). Palygorskite and attapulgite [13] are synonymous, palygorskite being the preferred name. The differentiation between sepiolite and palygorskite is the substitution of iron for magnesium, which causes some minor structural differences. These minerals consist of double silica tetrahedral chains linked together by octahedral oxygen and hydroxyl groups containing aluminum and magnesium ions. An electron micrograph of palygorskite is shown in Figure 10.

Figure 9. Structure of palygorskite (attapulgite), $(OH_2)_4(OH)_2Mg_5Si_8O_{20} \cdot 4\ H_2O$

○ H_2O; Dashed circle: Hydroxyl; ○ Magnesium or aluminum; ⊙ OH_2; ○ Oxygen; ● Silicon

Figure 10. Scanning electron micrograph of palygorskite (attapulgite)

Mixed-layer clays are mixtures of the unit layers on a layer-by-layer basis and are relatively common in nature. Illite – smectite, illite – chlorite, smectite – chlorite, vermiculite – illite, and even smectite – kaolinite have been described. Mixed-layer clays with both random and regular layering were treated by REYNOLDS [14].

[Top of Page]

3. Geology and Occurrence of Major Clay Deposits

Certain clays, such as kaolins, smectites, and palygorskite and sepiolite, can be found in relatively pure occurrences or can be beneficiated to relatively high purity. These particular clays have special industrial applications. Illites and chlorites are usually in shales or clays that are used for structural clay ceramics; they are not utilized where the application depends on the particular physical or chemical properties of the individual clay mineral.

3.1. Kaolin

Kaolin is a rock term, a clay mineral group, and an industrial mineral commodity. It is used interchangeably with the term china clay. The term kaolin is derived from the Chinese word *kauling*, meaning high ridge, the name for a hill near Jauchau Fu in China where a kaolin clay was mined for many centuries. Kaolin is a clay that

1. consists of substantially pure kaolinite or related clay minerals;
2. is naturally or can be beneficiated to be white or nearly white;
3. fires white or nearly white; and
4. is amenable to beneficiation by known methods to make it suitable for use in whiteware, paper, rubber, paint, and similar uses.

The term is applied without direct relation to the purity of deposits. Many large kaolin deposits are essentially pure and require little concentration during preparation for market. Most, however, are slightly off-color and require beneficiation to improve the brightness and whiteness and to control the particle size. Other kaolins contain as little as 10 % kaolinite; these must be washed and concentrated to recover a marketable product.

Kaolin deposits are classed as primary or secondary. Primary or residual kaolins are those that have formed by the alteration of crystalline rocks such as granite and remain in the place where they formed. Secondary deposits of kaolin are sedimentary and have been transported from their place of origin and deposited in beds or lenses associated with other sedimentary rocks such as sands. Kaolins occur on every continent, but only a few (Georgia, England, Brazil, Czechoslovakia, Eastern Germany, Spain, the former Soviet Union, and Australia) can be mined and beneficiated to meet the rigid industrial specifications required for use as a filler, extender pigment, or ceramic raw material. Only those in Georgia, England, and Brazil can meet specifications for coating clays for paper. Over half of the world's kaolin is produced in the United States and England.

The largest kaolin producing district in the world is located in Georgia and South Carolina in the United States. These deposits are late Cretaceous and early Tertiary [15] (Table 1) and occur in lenses and beds in relatively coarse sands (Fig. 11). The kaolin was derived from granitic rocks on the Piedmont plateau that were altered by weathering over a long period of geologic time. During the Cretaceous period, the Piedmont was uplifted, and the weathered residue consisting of kaolinite, quartz, feldspar, mica, traces of iron and titanium minerals, and organic matter was transported by streams onto a deltaic platform where it was deposited as sinuous lenticular deposits in lakes, oxbows, and swamps along the Cretaceous shoreline. The environment in which the deposition took place was similar to the one now existing along the coast of Georgia and South Carolina, with deltas, offshore bars, swampy, muddy lagoons, and winding estuaries. Extensive diagenetic alteration by ground water movement and oxidation has taken place since deposition. The deposits are concentrated in a belt ca. 30 km wide extending from central Georgia northeastward into South Carolina south of the fall line (Fig. 12).

Table 1. Geologic eras, periods, and epochs

Eras	Periods	Epochs	Years ago
Cenozoic	Quaternary	Holocene	
		Pleistocene	
	Tertiary	*Pliocene*

Figure 12. Location of kaolin deposits in Georgia and South Carolina

These minable sedimentary deposits range in thickness from 3 to 15 m and extend laterally from a few hundred meters to kilometers in length and width. The reserves of the coarser Cretaceous kaolins are being rapidly depleted and will probably last only another twenty or thirty years. However, the finer Tertiary kaolins are more abundant and the reserves will last for over a hundred years. The relatively coarse Cretaceous kaolins which are known as soft kaolins have a particle size that ranges from about 60 to 70 % finer than 2 µm, and the finer Tertiary kaolins which are known as hard kaolins range from about 85 to 95 % finer than 2 µm. In 2005, about 6.2×10^6 t of kaolin were produced in Georgia and South Carolina. The Georgia and South Carolina kaolins generally contain about 85 – 95 % kaolinite. The other minerals present are quartz, muscovite, biotite, smectite, ilmenite, anatase, rutile, leucoxene, goethite, and traces of zircon, tourmaline, kyanite, and graphite.

The English kaolins that occur in southwest England in Cornwall (Fig. 13) are primary. These kaolins are the result of alteration of large granite bodies by warm acidic hydrothermal solutions migrating upward along structural channels such as faults, fractures, and joints [16]. These warm solutions attacked the granite (Fig. 14), altering most of the feldspar and leaving quartz, mica, and tourmaline relatively unaltered. Superimposed on the hydrothermally altered granites is additional alteration by surface weathering. About 2 000 000 t of kaolin is produced currently from the Cornwall area. The mines are located in the area around St. Austell. Drilling has shown that kaolinization exists at depths over 800 feet (> 250 m) [17].

Figure 13. Location of kaolin deposits in southwestern England

° Working china clay pit

Figure 14. Cross section showing a hydrothermal kaolin deposit in granite in Cornwall

A large sedimentary deposit of kaolin of Pliocene age [18] is mined along the Jari River, a tributary of the Amazon, on the border of the states of Para and Amapa (Fig. 15). This deposit is 40 m thick and extends over an area of 60 km^2. This kaolin is fine in particle size, similar to the Tertiary deposits in Georgia and South Carolina. Currently 2005 about 900 000 t/a are being shipped from the Jari location in Brazil. The deposit is thought to be lacustrine in origin, and the kaolin was derived from weathering of the feldspathic granites on the Guyana shield. Kaolinite is the major mineral present, comprising 80 – 98 % of the deposit. The major nonclay mineral present is quartz, along with small amounts of gibbsite, zircon, rutile, anatase, ilmenite, tourmaline, and goethite.

Another large sedimentary kaolin area in Brazil is being mined and processed (Fig. 16). This kaolin is coarse, somewhat similar to the Cretaceous kaolins in Georgia. These Rio Capim crude kaolins are of exceptionally high quality [18]. As the Cretaceous kaolin deposits in Georgia become depleted, the Rio Capim kaolins will replace them in the world's paper-coating markets. Currently there are two kaolin operations along the Rio Capim producing about 1600 000 t/a. However, both plants are increasing their capacities, so that the annual tonnage will be about 2 000 000 in 2008.

Figure 15. Location of Jari kaolin deposit at Monte Dorado

Figure 16. Location of two kaolin mines in the Capim basin: Rio Capim Caulim (RCC) and Para Pigmentos (PPSA).

Former Czechoslovakia is the principal producer of kaolin in eastern Europe. The major kaolin deposits are located in the vicinity of Karlovy-Vary, Pilzen, and Podborany (Fig. 17). The kaolin is primary in origin, and the deposits are extensive, occurring as a weathering crust on crystalline rocks of the Bohemian Massif [19]. The parent rocks are granites and gneisses. The feldspar in these rocks is almost completely kaolinized. The major nonclay minerals are quartz and mica.

Figure 17. Locations of the major kaolin deposits near Karlovy Vary

1) Bo Žicany; 2) Sadov; 3) Otivice; 4) Sedlec; 5) Všeborovice; 6) representation in Karlovy Vary

In Germany, both primary and secondary deposits are being mined. In the eastern part of Germany, near Dresden, are two large primary deposits at Caminau and Kemmlitz [20]. These kaolins are the result of weathering of the Bohemian Massif which extends into this area of Germany. The major secondary or sedimentary deposits are in Bavaria near the village of Hirschau. The kaolin is the alteration product of feldspar contained in a Triassic arkose [21]. The deposit extends for about 15 km and ranges from 3 to 8 m in thickness. Kaolinite constitutes only about 5 to 15 % of the total minerals present, with quartz being the major mineral constituent along with partially altered feldspar.

Kaolin is mined in Spain in two locations. A Primary kaolin are mined in the northwestern corner of Spain in Galicia. These deposit are residues resulting from the weathering of a large granitic body [22]. A secondary or sedimentary kaolin of Cretaceous age is mined in the state of Guadalajara, east of Madrid. This kaolin is a minor constituent (10 – 20 %) in a friable white sand. There are extensive deposits of these kaolinitic sands extending from Guadalajara to Valencia [23].

In the Ukraine, a large primary deposit is being mined and processed near Proyanovski [18]. The kaolin is washed to remove quartz and mica, which are the major nonclay minerals present.

In Australia, both primary and secondary kaolin deposits are mined [25]. The largest primary deposit being mined is north of Melbourne near Pittong. The kaolin is a residual weathering product of altered granite. The major nonkaolin minerals are quartz and muscovite. There are large sedimentary kaolin deposits of late Cretaceous or early Tertiary age beneath bauxite on the Cape York Peninsula in extreme northeastern Australia. A deposit near Weipa was in production from 1986 to 1997 shipping about 100 000 t/a of a fine particle size kaolin to the paper markets in Japan, Southeast Asia, and Australia. This operation closed in 1997 because of quality problems and high production costs. Another deposit north of Weipa near the Skardon River is currently reported to be producing calcined kaolin [24].

In China, several kaolin deposits are being mined. The largest is located near Suzhou, southwest of Shanghai. The Suzhou deposit is primary, resulting from both weathering and hydrothermal alteration of granites and other acid igneous rocks [26]. The annual production from Suzhou is about 300 000 t/a. Other processing plants are located near Maoming in Guangzhou Province in southern China. This deposit is a very large sedimentary kaolinite sand containing about 80 % quartz and 20 % kaolinite [27].

Other kaolin deposits that are smaller and have low production are listed in the literature [28].

Ball clays and refractory clays are special types of kaolinitic clays that are used primarily for ceramics. Ball clays are secondary clays characterized by the presence of organic matter, high plasticity, high dry strength, long vitrification ranges, and light color when fired. Kaolinite is the principal mineral constituent of ball clay and typically makes up more than 70 % of this type of clay. Ball clays are mined in the United States [29], England [17], Germany [30], and Ukraine [30].

Refractory clays include several varieties of kaolinitic clays that are used in the manufacture of products requiring resistance to high temperatures [29]. Fire clay and refractory clay are used interchangeably by many authors, but NORTON [31] excludes white burning clays in his definition of fire clay. Refractory clays are common and are found on every continent except Antarctica, where they are probably present but have not yet been discovered.

3.2. Smectite

Smectite is the name for a group of sodium, calcium, magnesium, iron, lithium aluminum silicates, which include the individual minerals sodium montmorillonite, calcium montmorillonite, nontronite, saponite, and hectorite. The rock in which these smectite minerals are usually dominant is *bentonite*. The name bentonite was first suggested in 1898 by KNIGHT [32] and is the term commonly used to describe the industrial mineral. The term bentonite was defined by ROSS and SHANNON [33], who restricted it to a clay material altered from a glassy igneous material, usually a tuff or volcanic ash. WRIGHT [34] suggested that bentonite was any clay composed dominantly of a smectite clay mineral and whose physical properties are dictated by this clay mineral. GRIM and GUVEN [35] used WRIGHT's definition in their book on bentonites because there are many clays designated as bentonite that did not originate by the alteration of volcanic ash or tuff. Therefore, the term bentonite usually does not include the mode of origin.

Bentonites in which sodium montmorillonites are the major mineral constituent commonly have a high swelling capacity [36]. The largest and highest quality sodium bentonite deposits in the world are located in South Dakota, Wyoming, and Montana [37]. These clays are commonly called Western or Wyoming bentonites. The bentonite beds are Cretaceous and are part of the Mowry formation [37]. There are several bentonite beds in the Mowry, but the thickest and most extensive is the Clay Spur bentonite bed (Fig. 18). This Clay Spur bentonite bed extends west from Belle Fourche, South Dakota, and then north into Alberta, Canada (Fig. 19).

Figure 18. Diagrammatic sketch of the Clay Spur bentonite bed in the Mowry formation

Figure 19. Outcrop area of the Mowry bentonites

The Clay Spur bentonite usually ranges from 0.5 to 2 m thick, although thicknesses up to 4 m have been reported [38]. The bentonite is generally light yellowish green on the outcrop, becoming bluish green away from the outcrop. The highest quality swelling clay is the yellowish green bentonite, which has been weathered and oxidized. This Western bentonite was formed by alteration of volcanic ash. The major nonclay minerals present in the Clay Spur bentonite bed are quartz, opal-CT, feldspar, mica, and some zeolite. Locally calcite and gypsum may also be present.

Bentonites in which calcium montmorillonites are the major mineral constituent commonly have a low swelling capacity [36]. These clays are generally referred to as Southern or subbentonites. Large deposits of these calcium bentonites occur in Texas and Mississippi [35]. In Mississippi, the calcium bentonite occurs in the Eutaw formation of the Upper Cretaceous [39]. It is commercially produced in Itawamba and Monroe Counties, where some bentonites reach a thickness of 4 m. The bentonite is waxy and varies from blue when fresh to yellow when weathered. Quartz, feldspar, and micas are the major nonclay minerals present. Another calcium bentonite has been produced from the Tertiary Vicksburg formation in Wayne and

Smith Counties of Mississippi [40]. Several beds have been identified and are generally 0.5 – 1 m thick. This Tertiary bentonite ranges from white to gray to yellow. Quartz and micas are the major nonclay minerals. This central Mississippi bentonite is often referred to as the Polkville, Mississippi, bentonite.

The Texas calcium bentonites are found in a belt paralleling the present gulf coast in Cretaceous and Tertiary sediments. They are best developed in the Tertiary Jackson and Gueydan formations in Gonzales and Fayette Counties [41]. The mined bentonites range from 0.5 to 3 m thick. They vary from white to yellow to green to dark brown. Some of the white bentonites in Gonzales County contain kaolinite [42]. The major nonclay minerals are quartz, opal-CT, feldspar, and mica.

Other calcium bentonites are produced in the United States in Arizona, Alabama, and Nevada. The best known, most extensively mined deposit is at Cheto, Arizona, where a thick (5 m) ash bed in the Pliocene Bidahochi formation has altered to calcium montmorillonite [43]. The bentonite is white to light gray. This clay also contains a small amount of kaolinite. Quartz, micas, and feldspars are the common nonclay impurities. A small amount of calcium bentonite is produced from the Amargosa Valley in Nevada [44]. This bentonite is Pliocene in age and is white to light gray. The major nonclay minerals include quartz, mica, calcite, and dolomite. In Alabama, a calcium bentonite is produced at Sandy Ridge from the Ripley formation [45].

Some special bentonites, including hectorite and saponite, are produced in the United States. Hectorite, a lithium-bearing smectite, is mined at Hector, California. The hectorite was formed where siliceous lithium – fluorine solutions reacted with carbonates [46]. The hectorite deposits are Tertiary. Saponite is mined in the Ash Meadows area of the Amargosa Valley in Nevada. It is called Pliocene [44], although DENNY and DREWES [47] mapped these rocks as Pleistocene.

Bentonites are produced in many other areas of the world and are commonly of the calcium montmorillonite variety. In England, there are two well-known occurrences of smectites, which are of the calcium montmorillonite variety. In the English literature, they are referred to as *fuller's earth*. The term fuller's earth refers to any natural material that has the capacity to decolorize oil to an extent that is of commercial value (also see Palygorskite and Sepiolite) [35]. At Redhill in Surrey, near London, is a calcium bentonite in the Upper Cretaceous [48]. The clay is waxy and blue. Another calcium bentonite, of the Jurassic period, is found in Somerset [49].

In the Federal Republic of Germany, there are extensive deposits of calcium bentonite in the vicinity of Moosberg and Landshut in Bavaria [50]. These Bavarian bentonites occur in a marine section of marls and tuffaceous sands in the Upper Miocene molasse. Some beds attain a thickness of 3 m. The bentonite is light yellow to gray and has a waxy appearance. These deposits are an important source of commercial bentonite in European and world markets.

In Argentina, a bentonite deposit near Neuquen is being mined primarily for use as a drilling mud and a bond for foundry sands [18]. A white sodium bentonite is being developed in northern San Juan Province near Rodeo. This deposit was formed by the hydrothermal alteration of volcanic ash and tuff [51].

In Greece, several of the volcanic islands contain bentonite. The most extensively developed deposit, a Pliocene calcium bentonite, is on the island of Milos [35].

In Hungary, bentonite has been produced for about 50 years and is now an important product. The most important deposits are located at Istenmezo, Nagyteteny, Band, Komloska, Mad, and Vegardo [52]. The last three are the result of hydrothermal alteration of rhyolites and pyroxene andesites associated with Tertiary volcanism; the first three are the result of alteration of tuff that fell into the sea and altered under marine conditions. These altered tuff deposits are Surmatian (Tertiary).

In Italy, important calcium bentonite deposits are located on the island of Sardinia. The Sardinian bentonites are of two types, hydrothermally altered trachytic tuffs and sedimentary bentonite of the Miocene, which is a marine-altered ash [53], [54].

In the territories of former Yugoslavia, there are several calcium bentonites produced commercially. These are located near Pula, Kutina, Laktasi, Kriva Palanka, and Petrovac. The Petrovac deposit is Triassic, and the others are Middle to Upper Tertiary [35]. These bentonites are altered ashes and tuffs [55].

In India, bentonite is produced in the Barmer district of Rajasthan near Akli and Hathi-ki-Dhani [56]. These are quite pure calcium montmorillonites up to 3 m thick. They are Lower Tertiary and are associated with calcareous sands and conglomerates.

In Japan, commercial bentonites are located in the Yamagata, Gumma Niigata, and Nagano Prefectures of northern Honshu and on Hokkaido. The deposits are Miocene and Pliocene, formed by alteration of ash, pumice, and tuff [57]. Some of the bentonites in the Gumma Prefecture are up to 5 m thick.

In the Republic of Georgia, near the capital city of Tbilisi, are two well-known bentonite deposits, Askana and Gumbri [35]. The Askana bentonite is part of a series of Eocene tuffs and breccias ranging in composition from trachytes to basalts. Both sodium and calcium montmorillonites are produced from the Askana deposit. RATEEV [58] believes the Askana bentonites are hydrothermal in origin. The Gumbri bentonite occurs in beds up to 8 m thick and is Cretaceous in age [59]. This bentonite was formed by the submarine alteration of volcanic glass.

Other bentonite deposits along with their geologic age and occurrence are described in [35].

3.3. Palygorskite and Sepiolite

Palygorskite and sepiolite are clay minerals with a chain structure. These include palygorskite and sepiolite. The name attapulgite is synonymous with palygorskite, but the more recent name attapulgite has been discredited as a mineral name. However, it is so prevalent in the literature that the term still persists.

These clays are sometimes referred to as sorptive clays because they have a large surface area and can absorb and adsorb many materials. The term *fuller's earth* is more or less a catchall term for clays or other fine-grained earthy materials suitable for bleaching and sorbent uses. It has no compositional or mineralogical meaning. The term was first applied to earthy material used in cleansing and fulling wool, thereby removing the lanolin and dirt [60]; thus, it acquired the name fuller's earth. Industrially the term fuller's earth is used quite often for any sorptive clay.

Palygorskite (attapulgite) is produced in the southeastern United States near the Georgia – Florida border in the vicinity of Quincy, Florida, and Attapulgus, Georgia, in Senegal near Dakar, in China at Mingguang in Anhui Province and at Xuyi in Jiangsui Province, and in the Ukraine [18]. Sepiolite is mined commercially in Spain, which has the largest deposits, in Turkey, and in Nevada in the United States. These clays are lathlike or elongate in shape (see Fig. 10). Sepiolite is structurally similar to palygorskite except the former has a slightly larger unit cell and the individual laths are ca. one-third wider [61]. This may be due to the presence of more iron substituting for magnesium in the lattice, because generally palygorskite has a higher iron content.

The palygorskite deposits in southeastern United States are of the Miocene age and were deposited in marine lagoons [62]. The clay ranges from 0.5 to 3 m thick and is gray to tan or brown. These deposits are mixtures of palygorskite and smectite with the palygorskite content higher in the southern part of the district (Fig. 20).

Figure 20. Fuller's earth deposits in Florida and Georgia

The palygorskite in Senegal [63] is a large deposit that extends from Theis, where it immediately overlies a commercial aluminum phosphate deposit, south-southwest about 100 km to the southern border of Senegal. This deposit has been in production for ca. 20 years. The age of the deposit is early Eocene, and the thickness ranges from 1.5 to 6 m. The overburden thickness is low, usually less than 2 m. The color of the palygorskite is light tan to gray green. There are calcite, dolomite, and chert impurities in some areas. Smectite is also a common constituent, but in some areas it is barely detectable on X-ray diffraction patterns.

In Russia, palygorskite was first described in the Urals in the Palygorsk Range [64]. Palygorskite is mined in the Ukraine in the central part of the Ukrainian crystalline massif along the borders of the Cherkassay and Kiev regions. The palygorskite occurs in the middle section of a productive bentonite and is Lower Miocene [64]. The thickness of the palygorskite layer is ca. 2 m. Smectite, hydromica, and quartz are the other major constituents.

Palygorskite is produced in two areas of China, at Mingguang in Anhui Province and at Xuyi, which is directly north of Nanjing in Jiangsui Province. At Mingguang, the palygorskite occurs directly under a basalt and ranges between 4 and 6 m in thickness [18]. Near Xuyi the palygorskite is very near the surface (under a smectite rich layer that is 1 – 2 m thick) and is about 6 m thick. There are lenses of a light tan dolomitic palygorskite interspersed in the palygorskite at Xuyi. The ages of these two palygorskites are Middle Miocene, and the reserves at both locations are very large.

Sepiolite is mined in Spain near Toledo from a large Tertiary lacustrine deposit [65]. It is light tan and ranges from 1 to 5 m thick. Palygorskite is mined at Trujillo in the province of Caceres in western central Spain.

Sepiolite is mined in small quantities in the Ash Meadows area in the Amargosa Valley in Nevada [66]. The sepiolite occurs as 0.3 – 1 m stringers in saponite clays of lacustrine origin. The sepiolite is lightweight, very porous, and brown to brownish gray. The age of these sepiolite beds is Pliocene or Pleistocene [44], [47].

Sepiolite is produced in Turkey in the vicinity of Eskisehir in Anatolia [61]. The sepiolite is white and is interbedded with palygorskite shales. The sepiolite contains up to 3 wt % organic carbon in the form of humic acid, which enhances the dispersability of the clay.

Palygorskite is produced in the Mudh District in India [67]. The deposits are Tertiary and occur between fossiliferous limestones, thus apparently marine in origin. The thickness averages ca. 1.5 m.

Sepiolite is mined in Somalia where it is used to produce carved figurines and other art objects.

3.4. Miscellaneous Clays

Illite or chlorite deposits are not individually mined because they are normally mixed together and with other clay and nonclay minerals. Many clays and shales contain these clay minerals and are used for structural clay products, lightweight aggregate, and cement. Generally, clays and shales that contain illite and chlorite in major proportions have properties that are important in the manufacture of structural clay products. Structural clay products are a broad category that includes brick, drain tile, sewer piper, conduit tile, floor tile, wall tile, terra cotta, and other items (⟶ Construction Ceramics). The properties that are important in the manufacture of structural clay products are plasticity, green strength, dry strength, drying and firing shrinkage, vitrification range, and fired color. These physical properties depend on the constituents of the clay and their grain size [68].

Illitic and chloritic shales and clays are not restricted geologically and can be found in many areas of the world. In the United

States, shales and clays with high illite and chlorite content are found in all geologic periods with a preponderance in Pennsylvanian, Cretaceous, and Tertiary formations. Usually these clays and shales are relatively thick with low overburden.

Lightweight aggregate is a material produced from clays and shales. The material is fired rapidly in rotary kilns or sintering machines up to the temperature between incipient and complete fusion. At this temperature, substances that release gas cause bloating and vesiculation after fusion has developed a molten jacket around the particle, which prevents the escape of the gas. The mineral content is important, i.e., the clay minerals and the minerals such as calcite or dolomite that produce a gas on firing [69]. Clays and shales used for lightweight aggregate production are found in many areas of the United States and again are not restricted geologically or geographically.

Large quantities of clays and shale are used in the manufacture of cement. These clays and shales provide silica and alumina for the cement charge. Practically all clay or shale with an average alumina and silica content can be used in the cement industry. Usually these clays and shales can be found in the area in which the cement is being manufactured (→ Cement).

[Top of Page]

4. Mining and Processing

Almost all clay is mined by open pit. There are a few underground mines; however, in most instances the cost of production and poor roof conditions prohibit underground mining of clay deposits unless the clay has exceptional properties.

An understanding of the geology and the origin of a particular type of clay plays an important part in clay exploration. After a clay deposit is discovered, it must be evaluated to determine the quantity and quality of the clay. In most instances, this is done by core drilling and testing the recovered cores [70]. The spacing of the drill holes depends on the geologic and surface conditions associated with the deposit. For example, the drilling pattern used to evaluate a sedimentary kaolin deposit is much different than that used to evaluate a residual or hydrothermal kaolin deposit.

A small section that is contaminated with a deleterious material can affect the results of the total length of the core if it is composited. For this reason, the core is normally tested in increments of a meter or less. If the core is 5 m long, the core is composited for testing in five increments. In this way, a section that does not meet a particular specification can be isolated. Further drilling can corroborate the thickness and extent of the material that is out of specification, and a mining plan can be designed to handle the particular problem. Drilling is normally done on a pattern grid so that maps indicating thickness of overburden and thickness and quality of clay can be prepared.

4.1. Kaolin

All kaolins that are used as paper coating clays and most that are used as filler clays are processed because practically no deposits are naturally pure. Usually beneficiation is accomplished by one of two basic processes, a dry process or a wet process [70]. The higher quality grades of kaolin, except for some kaolins with special ceramic properties, are prepared by wet processing because the product is more uniform, relatively free from impurities, and of better color.

Major kaolin processing developments and their significance to the growth of the kaolin industry have been summarized [71]. There has been a steady growth of the kaolin industry since 1930, and the only physical property that has not been significantly improved by process developments is viscosity.

4.1.1. *Dry Process*

The dry process [72] is relatively simple and yields a lower cost, lower quality product than the wet process. In the dry process, the properties of the finished kaolin reflect the quality found in the crude kaolin. Therefore, deposits containing the desired qualities of brightness, low grit content, and satisfactory particle-size distribution are located by drilling and testing.

The overburden on the kaolin is stripped by motorized scrapers and bulldozers or draglines, or shovels. Once the overburden is removed, the kaolin is mined by using draglines, shovels, or front-end loaders. The kaolin is transported to the processing plant in trucks. The kaolin is usually shredded or crushed and stored in large storage sheds. Usually the kaolin is segregated into two or three bins according to specific properties, such as brightness and grit percentage. (Grit is material, usually quartz, that is coarser than 44 μm, i.e., the material that is retained on a 325-mesh screen.) The general flow sheet utilized in dry processing is shown in Figure 21.

Figure 21. Dry-process flow sheet for kaolin production

The material, as it enters the storage shed or enters the process, is shredded or crushed to particles equal to or less than the size of an egg. Normally, the crude kaolin contains ca. 20 – 25 % moisture and, therefore, must be dried. This is commonly done in a rotary dryer. After drying, the kaolin is disintegrated in a roller mill, hammer mill, disk grinder, or some other disintegrating device. Commonly, heat is applied to the kaolin during the disintegration to further reduce the moisture content. The disintegrated kaolin may then be air-classified to separate the fine particles from the coarse. The top size can be controlled to a degree so that various grades, based upon particle size, can be produced. The material is shipped in bulk or

in bags by truck or railcar.

4.1.2. *Wet Process*

The general flow sheet for wet processing Georgia kaolin [73] to produce both filler and coating grades is shown in Figure 22. The kaolin is mined with shovels, draglines, motorized scrapers, or front-end loaders and can be either transported to the processing plant or fed into a stationary or mobile blunger (Fig. 23). The blunger separates the kaolin into small particles, which are mixed with water and a dispersing chemical to form a clay – water slip or slurry. The dispersing chemical can be sodium polyphosphate, sodium silicate, or sodium polyacrylate, each of which can be blended with soda ash to reduce cost.

Figure 22. Wet-process flow sheet for kaolin coating and filler production

Figure 23. Dragline feeding kaolin into a mobile blunger

The percent solids of the slurry is normally between 30 and 40 %, but in some special circumstances it can be in excess of 60 % and as high as 70 % solids (see Section Combined Dry and Wet Processing). This clay – water slurry is pumped from the blunger to rake classifiers or hydrocyclones and screens to remove the grit. The grit is removed from the kaolin slurry and discarded into waste ponds or into mined-out areas. The degritted slurry is collected in large storage tanks with agitators and is then pumped to the processing plant, which may be several miles away.

The kaolin slurry is collected in large storage tanks at the plant before it is processed. Although each kaolin producer may process the kaolin slightly differently, the steps in the processing are generally as shown in Figure 22. The first step is to separate the kaolin particles into a coarse and fine fraction through continuous centrifuges. Some operators pass the degritted slurry through a high-gradient magnetic separator prior to centrifugation to upgrade the crude clay by removing iron and titanium minerals (see Section Special Processes).

The coarse fraction can be used as a filler in paper, plastics, paint, and adhesives, as a casting clay for ceramics, or as a feed to delaminators, which can be a subsequent processing step to produce a special paper coating grade (see Section Special Processes). The fine particle size fraction is used in paper coatings, high-gloss paints, inks, special ceramics, and rubber. As shown in Figure 22, there are many different steps that can be taken after the clay is fractionated. Normally, the coarse kaolin takes one of two routes:

1. It can go directly to the leaching department, where it is chemically treated to solubilize some of the iron if the brightness needs to be upgraded, or it can be flocculated so that the dewatering step is facilitated.
2. It can go through magnetic separation and into the delaminators or directly to the delaminators and then to the magnetic separator or to the delaminators without any magnetic separation step.

In the leaching operation, the kaolin slurry is acidified with sulfuric acid to a pH of ca. 3.0 to solubilize some of the colloidal iron. Sodium dithionite, a strong reducing agent, is then added to reduce the iron to the iron(II) state, which is more soluble and forms a clear iron sulfate that is removed with the filtrate in the dewatering step. In some cases, the iron in the kaolin is in a reduced state rather than the normal oxidized state. Usually such kaolins are slightly gray. These gray kaolins are treated with a strong oxidizing agent, such as ozone or sodium hypochlorite, prior to acidification and the normal reduction leach procedure. To facilitate flocculation prior to dewatering, in many cases alum is added along with the sulfuric acid.

At this point in the process, the kaolin slurry is between 20 and 30 % solids and is flocced. This flocced slip is then dewatered, which raises the solids to ≥ 60 %. The dewatering is accomplished by large rotary vacuum filters or plate and frame filter presses. The dewatered filter cake is then prepared for drying by using rotary, apron, drum, or spray dryers. Most of the clay that is shipped in dry bulk form is spray dried in a dispersed state. The usual process is to take the filter cake, which is flocced, and disperse it by adding a long-chain sodium polyphosphate or sodium polyacrylate. This dispersed high-solids slurry (≥ 60 %) is fed into the spray dryer, where it is sprayed or atomized and dried to meet the final moisture specifications, which normally range from less than 1 % to as high as 6 %. This dispersed clay slurry can also be dried by rotary drum dryers for some special uses that require the flake form.

Slurry clay, which is normally shipped in tank cars or trucks at 70 % solids, is produced by mixing the dispersed clay from the filters with enough spray-dried clay to bring the final solids to 70 %. Another process to bring the solids to 70 % is to use large evaporators. About 70 % of all shipments of coating and fine filler clays to the paper industry is now being shipped in slurry form.

If the filter cake is to be dried with rotary or apron dryers, then the filter cake is extruded into noodles ca. 3/8 in. (1 cm) in diameter and fed into the rotary dryer or onto an apron dryer. The final moisture from these dryers is generally ca. 6 %. This type of clay can be shipped in lump form, or if necessary, the clay can be further dried and disintegrated, using hammer mills swept with hot air. The final moisture of this disintegrated kaolin is ≤ 0.5 %. It is commonly referred to in the kaolin industry as acid clay because the pH is ca. 4.5.

The wet processes are used on the sedimentary kaolins in Georgia and Brazil. Primary kaolins such as the English china clays produced in the Cornwall district of southwest England are wet processed in much the same manner as the Georgia kaolins except for the mining methods. The kaolin content of the weathered granites ranges from 10 to 20 %. Mining uses high-pressure hydraulic monitors that play a stream of water on the mine face, washing out the fine particle kaolin and leaving the coarse quartz and mica residue. The fine kaolin is suspended and is transported in small rivulets to a collecting basin in the bottom of the open pit. This slurry is pumped to large thickeners, where the clay slurry is concentrated, and then processed generally following Figure 22.

4.1.3. *Combined Dry and Wet Processing*

A sort of hybrid development, a blend of dry processing and wet processing, is the whole clay slurry produced from fine particle size East Georgia Tertiary crude kaolins. Two processes are used to produce this high-solids whole clay slurry. One is to dry process the kaolin and then slurry the product at 70 % solids and degrit the clay slurry with a scalping cut on a centrifuge. A second method is to blunge the crude clay at high solids (65 – 68 %), degrit with a centrifuge, and add dry clay to bring the solids to 70 %.

4.1.4. *Special Processes*

Several special processes are used to produce unique and special quality grades of kaolin. One of these special processes is *delamination*, which is a process that takes a large coarse kaolin stack and separates it into several thin, large-diameter plates (Fig. 24). These thin, large-diameter plates have excellent covering power on rough base sheets of paper and are also used to produce high-quality lightweight coatings.

Figure 24. Diagrammatic representation of delamination of a kaolin stack into large thin kaolin plates

The process of delamination involves attrition mills into which fine media, such as glass beads or nylon pellets, are placed along with the coarse kaolin stacks and intensely agitated. The fine media impact the kaolin stacks, separating them into thin plates [74]. The brightness and whiteness of the delaminated kaolin is very good: the clean newly separated basal plane surfaces are white because they have been protected from groundwater and iron staining. The delamination process has enabled the kaolin industry to convert low-priced coarse clay into a higher priced special coating and filler clay.

Another special process is *ultraflotation*, which is a special flotation process to remove iron and titanium contaminants to make a 90 % brightness kaolin product [75]. *Selective flocculation* [76-78] is another special process that produces a 90 % brightness kaolin product by selectively removing iron and titanium impurities.

High-gradient magnetic separation (HGMS) is another special process, although it has become a standard processing technique in the kaolin industry. The high-gradient magnetic separation process [79] uses a canister filled with a fine stainless steel wool that removes iron, titanium, and some mica minerals from the kaolin slurry as it passes through the canister (Fig. 25). The process can be used to upgrade marginal low-brightness crude kaolins and to produce high-brightness coating clays. It also reduces the amount of chemicals that are needed to leach out the iron in a subsequent processing step. The development of HGMS has dramatically increased the usable reserves of kaolin in Georgia. Superconducting cryogenic magnets with field strengths up to 5 T are now being used in addition to the 2 T electromagnets. The superconducting magnets use very little power and are effective in removing ultrafine paramagnetic minerals [80].

Figure 25. Diagrammatic sketch of a high-gradient magnetic separator

A) Top view: a) Canister wall; b) Steel-wool matrix; c) Magnet coil; d) Magnet steel

B) Side view section through magnet: a) Canister; b) Magnet coil; c) Matrix; d) Magnet steel

Calcining is another special treatment that is used to produce special grades. One grade is thermally heated to a temperature just above the point where the structural hydroxyl groups are driven out as water vapor, which is between 650 and 700 °C. This produces a bulky product that is used as a paper coating additive to enhance resiliency and opacity in low basis weight sheets. A second grade is thermally heated to 1000 – 1050 °C. By proper selection of the feed kaolin and careful control of the calcination and the final processing [81], the abrasiveness of the calcined product can be reduced to acceptable levels. The brightness of this fully calcined, fine-particle kaolin is 92 – 95 %, depending on the feed material. It is used as an extender for titanium dioxide in paper coating and filling and in paint and plastic formulations.

Another special process is *surface treatment*. Kaolin is hydrophilic and can be easily dispersed in water. Because of the nature of the kaolinite surface, it can be chemically modified to produce hydrophobic and organophilic characteristics. Generally, an ionic or a polar nonionic surfactant is used as a surface treating agent. These surface-modified kaolins are

used in paper [82], paint [83], plastics [84], and rubber [85].

4.2. Smectite

Virtually all bentonite, which is comprised mainly of a smectite mineral, is strip-mined. Bulldozers and motorized scrapers are most commonly used for removing overburden. In a typical open pit, the overburden is removed in panels. The exposed bentonite is then mined by loading the material into trucks with draglines, shovels, or front-end loaders. Once the bentonite is removed, the overburden from the next panel is shifted to the mined-out panel.

Thicknesses of removed overburdens vary considerably. Most Wyoming-type bentonite has 10 m or less overburden. The thickness of overburden removed from some Mississippi bentonite deposits is as much as 30 m [86], about the same as that on some of the Arizona bentonites near Chambers. In Bavaria, some overburden on the bentonites is up to 50 m thick.

Bentonite beneficiation and processing involves relatively simple milling techniques that involve crushing or shredding, drying, and grinding and screening to suitable sizes (Fig. 26). The high-swelling Wyoming or sodium bentonites contain ca. 30 % moisture when delivered to the plant. The Southern or calcium bentonites have ca. 25 % moisture. The processed bentonite generally contains only 7 – 8 % moisture, although because bentonite is hygroscopic, it may contain considerably more moisture when used.

Figure 26. Flow sheet for bentonite production

The raw bentonite is passed through some sort of crushing or shredding device to break up the large chunks before drying. Drying in most plants is accomplished by gas- or oil-fired rotary dryers, but in one bentonite plant in Wyoming, a fluidized-bed dryer is used. The bentonite properties can be seriously affected by overdrying, so the drying temperature must be carefully controlled.

The dried bentonite is ground and sized in several ways. Granular bentonite is cracked by using roll crushers and screened to select the proper size range of granules. Most powdered bentonite is ground with roll or hammer mills to ca. 90 % finer than 200 mesh. The bentonite is shipped mainly in bags, but some is shipped in bulk.

Special processing is used in some plants to produce special products. Extruders can be used to pug the clay and mix it with additives that may improve the viscosity and dispersion properties. Some hectorite and Southern bentonites are beneficiated wet. In this process, the bentonite is dispersed in water and degritted by centrifuges, hydrocyclones, settling devices, or screens. The slurry is either filtered and then flash-dried or sent directly to rotary drum or spray dryers.

Organic-clad bentonite is bentonite that is processed to replace the inorganic exchangeable ions with alkylamine cations, which produces a hydrophobic clay [87]. These organic-clad bentonites are used in paints, greases, oil-base drilling muds, and to gel organic liquids.

Acid-activated bentonites are special sorptive clays used for bleaching edible oils and decolorizing special lubricating oils. The process flow sheet for acid activation is shown in Figure 27. The process involves slurrying the bentonite in warm water, removing the grit by hydrocyclones, reacting the clay with either sulfuric or hydrochloric acid at elevated temperature, dewatering in plate and frame filter presses, and flash drying. A dry activation process is also used and involves adding concentrated sulfuric acid to the clay in a blender and then pulverizing and drying the acid – clay mixture to ensure uniform distribution of the acid on the clay. Acid treatment removes some of the aluminum, magnesium, and iron octahedral ions, resulting in a highly charged particle saturated with hydrogen ions, which makes for a good bleaching and decolorizing clay.

Figure 27. Flow sheet for producing acid-activated bentonite

4.3. Palygorskite and Sepiolite

The mining of palygorskite and sepiolite clays is no different than mining bentonites. The processing is also similar (Fig. 28). The hormite clay is shredded or crushed, dried, screened, air-classified, and packaged. Some of this hormite clay is thermally treated to harden the particles to prevent disintegration of the granules during bagging, transport, and handling prior to arrival at the customer. The temperature of this thermal treatment is less than 400 °C so that no structural modification results, but all of the adsorbed water is driven from the surface and interior of the particles.

Figure 28. Flow sheet for producing palygorskite

When palygorskite (attapulgite) is to be used for salt-water drilling mud, the clay is extruded at high pressure through small orifices. This shears apart the bundles of palygorskite into individual elongate particles, which produces a higher viscosity drilling fluid.

[Top of Page]

5. Properties and Uses

Kaolins, smectites, palygorskite and sepiolite, and miscellaneous clays form an important industrial minerals group. Because of their fine particle size, particle shape, and surface chemistry, they have unique colloidal and physical properties.

5.1. Kaolin

Kaolin is one of the most versatile of the industrial minerals [88] and is used extensively for many applications [89]. It is a unique industrial mineral because it

1. is chemically inert over a relatively wide pH range (except for catalytic activity in some organic systems);
2. is white or near white;
3. has good covering or hiding power when used as a pigment or extender in coating and filling;
4. is soft and nonabrasive;
5. has low conductivity of both heat and electricity; and
6. is lower in cost than most materials with which it competes.

Some uses of kaolin require rigid specifications, including particle size, brightness, color, and viscosity. On the other hand, some uses have no critical specifications, e.g., cement, where the only concern is light color and chemical composition. Ceramic specifications are variable in that individual users may have different requirements as to strength, plasticity, fired color, shrinkage, and pyrometric cone equivalent (PCE). The major process industries in which kaolin finds a substantial use are paper, paint, ceramics, rubber, plastics, ink, catalyst, and fiberglass, as well as some special uses.

5.1.1. *Physical Properties*

Diagnostic tests are used to evaluate kaolin physical properties [90]. Some properties that can be used as screening tests for the many potential uses for kaolin are as follows:

mineralogy
screen residue (grit)
particle-size distribution
brightness
viscosity
pH

Mineralogy. The mineral content of a kaolin is important in assessing the uses, the results of many tests determining the physical properties, and the beneficiation processes that may be needed to produce a saleable product. X-ray diffraction of the whole sample gives a quick assessment of the gross mineralogy, but in many instances minor quantities of illite and smectite are not detected. Separation of the 2-μm and 0.5-μm fractions and preparation of oriented slides for X-ray enhances the basal reflections of the clay minerals and enables the detection of very small quantities of smectite and illite.

The presence of quartz, opal-CT, alunite, smectite, illite, muscovite, biotite, chlorite, gibbsite, feldspar, anatase, pyrite, iron oxides and hydroxides, and halloysite affects the beneficiation processes and the possible uses of the kaolin. In many instances, the presence of halloysite in a kaolin cannot be detected by X-ray diffraction; therefore, electron micrographs and differential thermal analysis must be used.

Screen Residue. The grit test gives the percentage of particles that are retained on a 325-mesh screen (44-μm openings). Quartz and mica, along with hard agglomerates of kaolin, are the most common minerals retained on the screen. The amount of screen residue is important in estimating the recovery of the minus 325 mesh material since this is the fraction that is the usable portion of the kaolin. Generally, if the kaolin contains more than 5 – 8 % grit, it cannot be dry processed.

Particle-Size Distribution. Particle-size distribution (Fig. 29) is one of the more important properties of a kaolin because it affects viscosity, brightness, opacity, gloss, ceramic strength and shrinkage, and many other properties. Sedimentation methods based on Stoke's law of settling are used for measuring particle size. The 2-μm content of a kaolin is particularly important because it is this fraction that constitutes the major portion of paper coating clays and high-glossing paint clays. The particle-size distribution also determines the beneficiation procedures that are used in processing a kaolin for industrial uses.

Figure 29. Particle-size distribution of some typical kaolin coating and filler grades

Brightness. The brightness of a kaolin is an important property because it determines the potential uses and prices. In general, the higher the brightness of the kaolin the more value the kaolin has. Standard brightness values are measured at a wavelength of 457 nm, and a common standard against which the samples are compared is smoked magnesium oxide. As a general rule, filler clays have a brightness of 80 – 85 %, and paper coating clays and high-glossing paint clays have a brightness of 85 – 93 %.

Viscosity. The flow properties of kaolin used for paper coating are very important. Both low-shear and high-shear viscosity measurements are made at 70 – 71 % solids. Low-viscosity kaolins are required for paper coating because the kaolin coating color must flow easily as it is applied to the paper surface, not leaving streaks or blotches, which can be caused by high-viscosity coating colors.

pH. The pH of untreated kaolin slurries normally ranges from 4.5 to 6.5. A high pH generally indicates the presence of soluble salts that can cause problems in many applications.

5.1.2. *Paper*

The mineral kaolinite has many physical properties that are advantageous to the paper industry. It is white, fine, soft and nonabrasive, and relatively inert. In the United States, ca. 70 % of all of the wet processed kaolin is used by the paper industry as a coating clay and as a filler. Some physical constants that are representative of kaolins from Georgia are the following:

Specific gravity d_4^{20}	2.62
Index of refraction	1.57
Hardness (Mohs' scale)	1.5 – 2
Fusion temperature, °C	1850
Valley abrasion number	4 – 10
Dry brightness (at 457 nm), %	75 – 91
Crystal system	triclinic

The Georgia kaolins and English kaolins are the most widely used kaolins in the paper industry. Table 2 lists typical chemical analyses of two Georgia kaolins and an English kaolin, two Brazilian kaolins, and theoretical kaolin.

Table 2. Typical chemical analyses, wt %

Component	Cretaceous middle Georgia kaolin	Capim soft kaolin	Tertiary east Georgia kaolin	Jari hard kaolin	English kaolin	Theoretical kaolin
SiO_2	45.30	46.56	44.00	44.45	46.77	46.3
Al_2O_3	38.38	38.03	39.5	37.37	37.79	39.8
Fe_2O_3	0.30	0.59	1.13	1.93	0.56	
TiO_2	1.44	0.78	2.43	1.39	0.02	
MgO	0.25	0.01	0.03	0.02	0.24	
CaO	0.05	0.01	0.03	0.01	0.13	
Na_2O	0.27	0.03	0.08	0.01	0.05	
K_2O	0.04	0.02	0.06	0.12	1.49	
Ignition loss	13.97	13.8	13.9	14.45	12.79	13.9

Important Properties. *Particle-size* and *shape distribution* are probably the most important factors in controlling the many physical properties of kaolin important to the papermaker. Figure 29 shows the range of particle-size distributions available commercially. The 2-µm size is used as the commercial control point. The coarse particle size kaolins are normally used as filler clays, and the fine particle size kaolins are used as coating clays.

Some of the properties of importance to the papermaker are dispersion, rheology, brightness and whiteness, opacity, gloss and smoothness, orientation, adhesive demand, film strength, and ink receptivity.

Complete *dispersion* of the kaolin particles is necessary to obtain maximum efficiency in a coating or filler clay. Kaolin is

easily dispersed because of its hydrophilic surface. In the natural state, kaolin is acid and is flocculated. This flocced state is the result of the presence of both positive and negative charges on the particles, which attract each other and form aggregates. Therefore, dispersing agents must be used to deflocculate the kaolin by making the particles all the same charge order, thus obtaining maximum fluidity. The most efficient dispersing agents for kaolin in aqueous systems are alkali-metal polyphosphates, polyacrylates, and silicates [91].

The *rheology* or flow properties of coating clays and coating colors are complex and exert a controlling influence on the coating operation. Such factors as coat weight, smoothness, and freedom from pattern on the coated sheet are related to viscosity. Low-viscosity kaolins can be dispersed (made down) readily at high solids concentration (71 %). In addition, these low-viscosity suspensions can be pumped and screened with relative ease. The coating process (i.e., trailing blade, roll coater, air knife, etc.), the coating color formula, the type and amount of adhesive, and the percent solids of the coating color determine the high- and low-shear viscosity values that can be tolerated for the coating clay.

Brightness and whiteness of kaolin coatings are controlled primarily by the presence of iron and titanium minerals in the kaolin. However, the coating structure is also important. Significant differences in refractive indices between coating components are necessary to obtain maximum light scattering and, thus, optimum brightness and whiteness. The coating structure must have a maximum of uniformly distributed air-filled pores. Differences in brightness of one percentage point of the dry kaolin powder may result in a difference of less than 0.2 % brightness of the coated sheet. Coating structure and weight, particle-size distribution, particle shape, and brightness and whiteness of the dry kaolin powder all affect the coated sheet brightness and whiteness.

Opacity of kaolin coatings is strongly influenced by particle packing, which depends largely on particle size and shape and particle-size distribution. Particle size and particle-size distribution must be optimal to develop efficient scattering of light and consequent opacity. The presence of ultrafine particles of ca. 0.1 μm seriously lowers the opacity [92]. The opacity of the coating layer depends on the difference in the refractive indices and the relative proportions of the various components, including air, pigment, and adhesive.

Gloss and smoothness are related to particle size and shape. Superior gloss is attained with kaolins of fine particle size. Smoothness is developed with fine, thin, small-diameter particles. The object of coating paper is to smooth over the fine structure of the base paper to make high-quality ink transfer possible.

Parallel *orientation* of the kaolin particles results in conformation to substrate irregularities, thus reflecting imperfections of the substrate surface. The method of application of the coating affects the orientation and, hence, the smoothness. For optimum effects on irregular substrates, the particle orientation should be random adjacent to the substrate and parallel at the top of the coating [93].

Coating clays are characterized by a low *adhesive demand*, ranging between 10 and 18 %. Finer particle size clays require slightly higher amounts of adhesive. The introduction of adhesive can disrupt orientation and reduce smoothness, gloss, and other optical qualities. The selective drainage of adhesive into the substrate or the concentration at the coating surface strongly affects the coating properties [93]. The adhesive requirement is directly related to the surface area of the clay. The amount of adhesive in the coating affects the opacity, brightness, color, and smoothness, as well as film strength. If the amount of adhesive is excessive, the printability is poor.

Film strength is related to preferential adhesive migration into the substrate and to the preferred orientation of the kaolin particles [94]. Maximum film strength is attained with well-oriented, dense films, which imply a highly bonded surface area. If pick occurs within the coating layer, it is generally caused by insufficient adhesive, excessive adhesive migration into the base sheet, or poorly dispersed pigment.

Kaolins are considered to have low ink absorption even though they readily accept printing inks. Substantial differences exist between the *ink receptivity* of coatings made from different grades of kaolin. This is related to film permeability, which is influenced by void volume. Thus, small-diameter particles that are randomly oriented give excellent ink receptivity. The interrelationship of the kaolin and adhesive is a major control over ink receptivity and holdout.

There are many grades of coating and filler clays available to the paper industry. The properties that define these coating and filler clays are based on brightness, particle size and particle-size distribution, and particle shape. Table 3 shows the major coating grades and their particle size and brightness.

Table 3. Particle size and brightness of Georgia coating kaolins

Grades	Mass fraction with particle size < 2 μm, %	Brightness, %
Regular coating clays		
No. 3	73	85.0 – 86.5
No. 2	80 – 82	85.5 – 87.0
No. 1	90 – 92	87.0 – 88.0
Fine no. 1	95	86.0 – 87.5
Delaminated coating clays		

Regular	≈70 – 80	88.0 – 90.0
Fine	≈90 – 95	87.0 – 88.0
High-brightness coating clays		
No. 2	80	89.0 – 91.0
No. 1	92	89.0 – 91.0
Fine no. 1	95	89.0 – 91.0
Special coating clays		
Low-glossing clays	≈50	87.0 – 88.0
Calcined extender	85	92.5 – 94.0

Coating Clays. The no. 3 and no. 2 grades are generally used in high-solids formulations for publication-grade paper and medium-finish lower cost enamels. Slick sheet magazines with large circulation are generally coated with one of these two regular grades often mixed with the regular delaminated grade. The no. 1 grade is used to coat high-quality boxboard and enamel papers. This grade gives excellent gloss and brightness and relatively uniform ink receptivity and good smoothness. The fine no. 1 grade is used where maximum gloss and very good ink holdout is desired.

The regular delaminated grade is used on lightweight paper and paper that has a rough surface where good printability must be maintained. This clay gives coatings that are exceptionally smooth with excellent ink and varnish holdout. The fine delaminated grade is used to achieve maximum gloss, good runnability, and high opacity.

The high-brightness grades, having a blue-white tint, are very bright. The coatings that use these grades are very smooth and give excellent gloss ink holdout and good printability. These high-brightness grades are used to coat premium-grade paper.

The special coating grades were developed to meet specific coating needs. The low-glossing coating clays are used when a dull or matte finish is required. The calcined kaolin extender is used to replace titanium dioxide in the coating to reduce the cost of the coating formulation and still maintain the desired optical properties.

Filler Clays. Fillers are highly desirable in printing papers because they increase the opacity, raise the brightness, increase the smoothness or finish, and improve the ink receptivity and printability. Filler clays also improve the appearance and absorbency of paper, as well as increase the density. A perfect filler, if available, would have the following characteristics [95]:

1. Reflectance of 100 % at all wavelengths of light
2. High index of refraction
3. Grit-free and a particle size close to 0.3 μm, approximately half the wavelength of light
4. Low specific gravity, soft, and nonabrasive
5. Ability to impart to paper a surface capable of taking any finish, from the lowest matte to the highest gloss
6. Complete retention in the paper web
7. Completely inert and insoluble
8. Reasonable in price

Obviously, such a perfect filler is not available, and filling paper is a matter of compromise. Kaolin is the usual filler in white or essentially white papers such as newsprint, printing grades, uncoated book, to develop certain desirable properties, and in paper may be the only filler used. In some grades, kaolin may be partially replaced by other mineral fillers to develop certain desirable properties, or may be used alone without clay.

In general, the lighter the weight of the paper, the greater the need for a filler to improve its opacity and brightness. Cost reduction is an important criterion for using fillers. In most cases, the filler is much less expensive than the pulp it replaces. Table 4 gives the filler grades of kaolin that are available.

Table 4. Filler grades of kaolin

Type	Brightness, %	Screen residue, %
Air-floated filler	80 – 81	0.30
Whole clay filler	81 – 83	0.10
Whole clay filler	83 – 85	0.10
Water-washed filler	81 – 83	0.09
Water-washed filler	83 – 84	0.09
Water-washed filler	84 – 86	0.05
Delaminated filler	86 – 87	0.005

High-brightness delaminated filler	87 – 89	0.005
Calcined kaolin extender	91 – 94	0.01

In general, filler grades are produced to meet brightness and grit specifications. The lowest price filler grade is air-floated, whereas the highest price filler grade is the calcined kaolin extender. A good review of the properties of paper affected by fillers is presented by CASEY [96] (⟶ Paper and Pulp).

5.1.3. *Paint*

Kaolins are used extensively in water-based paints. Kaolin is a functional extender pigment that has good covering or hiding power, imparts desirable flow properties to the paint, and is inexpensive. *Brightness* and *particle size* are important physical properties, as is a *resistivity specification*. A resistivity test gives an index of the amount of residual soluble salts that remain in the clay. Higher resistivity values reflect a low soluble salt content, which is important because high soluble salt content adversely affects the dispersion of the paint ingredients and alters paint properties.

Another important physical property is *oil absorption*, which gives an indication of surface area and which is related to a parameter called vehicle demand. A test commonly used by the paint manufacturer to measure dispersion is a fineness of grind measurement using a Hegman gage. Actual paint formulations are made, and many performance tests are run, including gloss, color, smoothness, flow characteristics, dispersion, stability, weathering characteristics, aging, washability, and hiding power.

The kaolins used in paint vary from very coarse, which produces a matte finish, to very fine, which gives a high-gloss finish. Calcined kaolins are used in paint as a titanium dioxide replacement and extender. Delaminated clays are used to give a high-gloss finish with good covering power, good color, and excellent washability (⟶ Paints and Coatings).

5.1.4. *Ceramics*

The ceramic industry is a large user of kaolin clays in whiteware, sanitary ware, insulators, and refractories. Several tests are used to evaluate kaolins for use in ceramics, including plasticity, shrinkage, modulus of rupture, absorption, fired color, casting rate, PCE (see Section Kaolin), and chemical analysis.

Coarseparticle-size clays are used for casting clays in sanitary ware, and fine-particle kaolins are used when high strength is important, such as in whiteware and as a bond in certain refractory applications. Ball clays, which are a fine-particlesize, very plastic kaolinitic clay, are used in whiteware, stoneware, enamels, etc. Calcined kaolin called grog is marketed to the refractory industry for use in high-alumina refractories. Both dry-process and wet-process kaolins are used by the ceramic industry (⟶ Ceramics, General Survey).

5.1.5. *Rubber*

Kaolin is used by rubber manufacturers because of its reinforcing and stiffening properties and because of its low cost. Fine-particle-size kaolins give good resistance to abrasion and are used extensively in nonblack rubber goods. The kaolins that are used in rubber contain a maximum of 1 % free moisture. Both dry-process and wet-process kaolins are used, but by far the largest tonnage are dry-process grades. Brightness, particle size, and grit percentage are important physical properties. Other tests that are important in evaluating kaolin for use in rubber are water settling characteristics and oil absorption. The water settling test gives a good idea of the reinforcing characteristics of the clay, and oil absorption also correlates with reinforcement. Tests on the clay-filled rubber itself are stress – strain, tear resistance, abrasion resistance, heat generation, energy rebound, extrusion and plasticity, hardness, aging characteristics, and water absorption [97] (⟶ Rubber, 4. Chemicals and Additives).

5.1.6. *Plastics*

Kaolin is used in plastics because it aids in producing a smooth surface finish, reduces cracking and shrinkage during curing, obscures the fiber pattern when fiberglass is used as reinforcement, contributes to a high dielectric strength, improves resistance to chemical action and weathering, and helps control the flow properties. Kaolin is a functional filler in that it contributes some beneficial effects. Loadings in various plastic compositions vary from ca. 15 % to as high as 60 % (⟶ Plastics, General Survey).

5.1.7. *Ink*

Kaolin clays are used extensively in printing inks. In black inks the pigment is normally carbon black, but in white and other colored inks kaolin is a common extender pigment. The kaolins used in ink must be fine particle size and relatively white. A major disadvantage to the use of kaolin in ink is its hydrophilic nature. However, coating the kaolin particles with hydrophobic material increases its usefulness in inks. Surface-modified kaolins have found a significant market in printing inks (⟶ Drawing and Writing Materials).

5.1.8. *Catalysts*

Kaolin clays are used extensively in the production of cracking catalysts and molecular sieves. The kaolin clay should have relatively low iron and sulfate content. Although the surface of the kaolin does contribute some catalytic activity, the kaolin serves largely as a diluent for the silica – alumina gels [98]. Partially calcined kaolins, which are heated to a temperature just above the dehydroxylation temperature of ca. 600 °C, are used in the manufacture of molecular sieves [99] (⟶ Heterogeneous Catalysis and Solid Catalysts).

5.1.9. *Fiberglass*

Kaolin clays with a low iron content are used as a source of alumina and silica in the manufacture of fiberglass. A good grade of air-float kaolin is generally used (⟶ Fibers, 5. Synthetic Inorganic).

5.2. Smectite

Smectite is a group name, and many minerals comprise the smectite group, including sodium montmorillonite, calcium montmorillonite, saponite, nontronite, hectorite, and sauconite. Each of these minerals has unique properties, and therefore, the individual smectite minerals and the other minerals that are present in the bentonite must be determined. This is done by X-ray diffraction, electron microscopy, differential thermal analysis, infrared spectrometry, and selective chemical analysis. Once the smectite mineral has been identified, then some of the properties can be established, for example, viscosity, thixotropy, plasticity, shrinkage, bonding strength, shear strength, and water impedance. These properties are not the same for all smectites and, in fact, are quite different.

The exchangeable cations present between the silica and alumina sheets (see Fig. 5) have a strong influence on the use and properties of the smectite. The major uses of smectites (bentonites) are in drilling muds, foundry sand bond, and iron-ore pelletizing. In addition to these three major uses, bentonite is used for many miscellaneous products, including filtering agents, water impedance, cosmetics, animal feed, pharmaceuticals, paint, ceramics, slurry trenching, catalysts, and decolorizing.

Drilling Fluids. Sodium montmorillonite, which is the major constituent of the Wyoming or Western bentonites, is a high-swelling clay with some unique properties. It is used throughout the world as an ingredient in drilling fluids because commonly this Western bentonite yields 100 barrels per ton (20 m^3/t) [35]. Only 5 % of this bentonite is necessary to produce the high viscosity, thixotropy, and low filter-cake permeability required in the drilling fluid. Hectorite, the lithium smectite, also gives high yields and has excellent properties as an ingredient in drilling fluids. Some calcium montmorillonites can be treated with a sodium salt, usually soda ash, to produce a bentonite suitable for use in drilling fluids, but in general such treatment does not substantially improve the water loss property of the bentonite.

Foundry Molding Sands. The molding sands used in foundries are composed of sand and clay. The clay provides bonding strength and plasticity. A small amount of tempering water is added to the mixture to make it plastic. It can then be molded around a pattern and be cohesive enough to maintain the shape after the pattern is removed and while molten metal is poured into it. The important foundry properties are green compression strength, dry compression strength, hot strength, flowability, permeability, and durability. These properties vary greatly with the amount of tempering water [35]. Both sodium and calcium bentonites (montmorillonites) are used as bonding clays. Calcium bentonite has a higher green strength, lower dry strength, lower hot strength, and better flowability than sodium bentonite. Final evaluations of the bonding clay can only be made after the bentonite is actually used in foundry practice so that flowability, durability, ease of shakeout of the casting from the mold, and cleanness of the surface of the cast metal can be determined. Commonly, blends of sodium and calcium bentonites are used to gain the optimum properties from each.

Iron-Ore Pelletizing. Bentonites are used extensively in pelletizing iron ores [100]. Finely pulverized ore concentrate must be pelletized into units of ca. 1 in. (2.5 cm) or more in diameter before it is used as blast furnace feed. Pelletized ore is a superior blast furnace feed. Bentonite is ca. 0.5 wt % of the ore. Because of its superior dry strength sodium bentonite is the preferred bentonite for pelletizing ores.

Other Uses. Acid-activated bentonites are widely used to *decolorize* mineral, vegetable, and animal oils. The clay also serves to deodorize, dehydrate, and neutralize the oils. In addition, the clay must have low oil retention and good filtration characteristics. It must not change the character of the oil nor give an objectionable taste to the oil. Some bentonitic clays naturally possess adequate decolorizing ability. Such materials are called fuller's earth. The bentonites that work best as both natural and acid-activation decolorizers are the calcium variety.

Some clay *catalysts* for cracking petroleum are produced from bentonites with very low iron content. The bentonite is reacted with sulfuric or hydrochloric acid at elevated temperatures followed by washing, drying, and calcining at ca. 500 °C. This process removes the adsorbed alkali metals and alkaline-earth metals along with the removal of iron and partial removal of magnesium and aluminum from the lattice. This increases the surface area and alters the pore-size distribution of the product. Calcium bentonite is the preferred material for making a smectite clay catalyst.

Sodium bentonites are used in *water impedance*. The clay is used to impede the movement of water through earthen structures such as dams, to stop seepage of water from ponds and irrigation ditches, and to stop water from entering basements of homes. One use of high-swelling sodium bentonite is in the slurry-trench or diaphragm-wall method of excavation in construction in areas of unconsolidated rock or soil [101]. In this method, the trench being excavated is filled with bentonite slurry, and the earth being excavated is removed through it. A thin filter cake on the walls of the excavation prevents loss of fluid, and the hydrostatic head of the slurry prevents caving and running of loose soil, which makes costly shoring unnecessary. Small amounts of sodium bentonites are added to cement to improve workability, lessen aggregate segregation, and enhance impermeability. Another growing use is for liners in landfills for waste disposal and for toxic wastes [104].

Sodium bentonites are widely used as *emulsifying* and *suspending agents* in many oil and water systems and in medicinal, pharmaceutical, and cosmetic formulations [102]. Sodium bentonites are used in both oil- and water-based paints. In water-based paints, the bentonite acts as a suspending and thickening agent. In oil-based paints, it is used as an emulsifying agent.

In *paper*, sodium bentonite is sometimes used in the deinking process to recover the cellulose fibers. These deinking processes generally involve heating the paper to be deinked in a caustic soda solution to break down the ink, thus freeing the ink pigment. Next a detergent is added to force the pigment from the paper fiber. Smectite is then added to disperse the pigment particles and adsorb them. Washing removes the smectite, which carries the ink pigment with it. Sodium bentonite is also used in papermaking to prevent the agglomeration of pitch, tar, wax, and resinous material. The addition of 0.5 %

smectite, based on the dry weight of the paper stock, prevents agglomerates so that the globules will not stick to screens, machine wires, and press rolls and thus cause defects in the paper.

Sodium montmorillonite is the base for the organoclays described earlier. The organoclad clays are used in lubricating greases, inks, paints, and oil-based drilling fluids. These clays improve pigment suspension, viscosity, and thixotropy control. They also improve brushability and spraying characteristics of paints [105]. Another area of research and utilization is to process sodium montmorillonite to produce nanocomposites for use in improving the physical properties of certain plastic compositions [106]

Calcium montmorillonite is used in adhesives; as granular pet litter; to clarify wines, cider, and beer; as floor absorbents; carriers and diluents in pesticide preparations; and in water clarification. White calcium smectites are used in detergents, paints, enamel suspensions, pharmaceuticals, cosmetics, food, pelletized animal feed, and in no-carbon-required copy paper [28].

Both calcium and sodium smectites are used as additives in ceramics, particularly because of their plasticity and relatively high green and dry strengths. For example, many brick clays are silty materials. The addition of a small amount of smectite improves the plasticity and green and dry strengths. In addition, both types are used as a liner for toxic and low-level radioactive waste disposal sites and as additives to latex for thickening and stabilizing.

5.3. Palygorskite and Sepiolite

The use of the palygorskite and sepiolite is almost as varied as that of the kaolins and smectites. Because of the particle shape of the these clays, i.e., palygorskite (attapulgite) and sepiolite are elongate (see Fig. 10), they have some special applications. The specific type can be identified with X-ray diffraction and is generally characterized by using scanning electron microscopy to determine the crystal size and length. In addition to the crystal shape, another set of important properties is the absorption and adsorption characteristics.

One of the more important, larger uses is *drilling fluids*. Considerable quantities of palygorskite and sepiolite are used in drilling fluids because the viscosity and gel strength of the mud are not affected by variations in electrolytic content as are those of muds comprised of bentonite. Thus, palygorskite and sepiolite drilling muds can be used with salt water or when formation brines become a serious problem. In recent years, the offshore drilling industry has used salt-water-based muds, so that the quantities of palygorskite and sepiolite used have increased dramatically.

Because palygorskite and sepiolite are not easily flocculated on account of their particle shape, these clay minerals are used as *suspending agents* in paint, medicines, pharmaceuticals, and cosmetics. In paint, palygorskite is used because it improves the thickening and thixotropic properties. Another major use is as *floor sweep compounds*, for absorbing oil and grease spills on factory floors, in service stations, and other areas where oil and grease spills are a problem. Granular particles of palygorskite are the most effective floor absorbent.

Palygorskite and sepiolite are also used extensively in *agriculture* as absorbents and adsorbents for chemicals and pesticides. The chemical is mixed onto the granular hormite clay particle, and the treated particle is placed in the ground with the seed particle. The pesticide or fertilizer chemical is slowly released to provide the necessary fertilizer or protection for the growing plant. Finely pulverized hormite clays are also used to adsorb chemicals, which can then be dusted or sprayed on the plant or on the surface of the ground. A growing application is to use palygorskite (attapulgite) to make suspension fertilizers.

Another large use for palygorskite and sepiolite is *pet litter*. Granular particles of are an effective litter for absorbing animal waste, particularly for domestic cats. The clay effectively absorbs the waste and odors.

HADEN [103] described the properties and uses of palygorskite and pointed out both the colloidal and noncolloidal characteristics that make this mineral important. Other uses of hormites include foundry sand binder, polishes, wax emulsions, metal drawing lubricants, laundry washing powders, bonding agents for granulation of powders, decolorizing oils, anti-caking agents, flattening agent in paints, catalyst in no-carbon-required paper, and catalyst carrier.

6. Environmental Aspects

Almost all clays are surface mined, so the industry is required to reclaim the disturbed land in most countries. Common practice is to open a cut and then spoil the overburden from the following panels or cuts into the mined out areas. The land is leveled or sloped to meet the governmental requirements and then planted with grasses or trees.

In the processing plants the waste materials, which include chemicals and separated clay particles or other minerals, are collected in impounds. The clay and other particles are flocculated with alum or other chemical flocculants, and the clear water is released into streams after adjusting the pH to 6 – 8.

Air quality is maintained in the processing plants by using dust collectors on the dryers and by enclosing transfer points where dry clay may cause dust. In areas such as the bagging departments, the workers may be required to wear dust masks. None of the clays, kaolins, smectites, or hormites are health hazards. Any dust, if inhaled in large quantities, can be a problem, but the industries use dust collectors and require workers to wear masks. Therefore, no serious lung ailments result. The clays themselves contain no deleterious trace elements or chemicals that are hazardous to human health.

[Top of Page]

7. Production and Consumption

Clays are important industrial minerals in most parts of the world. As indicated in Chapter Properties and Uses they are utilized in many process industries and are necessary ingredients in a great many products: kaolins are used in paper, ceramics, paint, etc.; bentonites, in drilling fluids and foundries; and palygorskite and sepiolite, in special drilling fluids and as suspending agents in paints and pharmaceuticals.

The total kaolin production in the world is about 40 × 10^6 t/a. The largest producer is the United States with about 6.2 × 10^6 t/a. The paper and ceramic industries are the largest consumers worldwide. Paper-coating kaolins are produced in Brazil, England, and the United States. The largest markets for these coating clays are in Europe, Japan, and North America.

Bentonite production is about 11.5 × 10^6 t/a in the world, and the United States has the largest production of ca. 6.2 × 10^6 t/a. The high-viscosity, high-swelling sodium bentonites from Wyoming, Montana, and South Dakota are exported around the world for use in drilling muds for oil and gas exploration, as high-strength foundry bond clays, and for pelletizing iron ore for shipment.

Palygorskite and sepiolite production in the world is ca. 2.8 × 10^6 t/a, and the United States is the largest producing country with ca. 1 × 10^6 t/a. Spain is the second largest producer with ca. 800 000 t/a. The largest consumers of these clays are pet litter, drilling muds, carriers for agricultural chemicals, and oil and grease absorbents.

No figures are available for the world production of common clays and shales but it is probably over 100 × 10^6 t/a. These common clays and shales are used extensively in most countries to make brick and other structural clay products.

In summary, clays are one of the most important and versatile industrial minerals. They are used in construction, agriculture, the many process industries, and environmental applications [107]. Clay minerals and materials are about the least expensive ingredients that are used in many products even though they are very functional. Some important value added products such as calcined kaolins, organoclays, and nanocomposites have been developed, and future research efforts will continue to develop new value-added products. The higher quality clays — kaolins for paper coating, sodium bentonite for drilling muds, and palygorskite and sepiolite for sorbent uses — are exported to markets all around the world, which continue to grow. Fortunately, the reserves of these clays are large so that the markets will continue to be served for the foreseeable future.

1. Household and Institutional Cleansing Products

For centuries, people cleaned pots, pans, kettles, and other household objects with fine sand, occasionally mixing it with wood ashes or soda. However, with the advent of goods fabricated from increasingly sensitive materials, including polished metal, painted wood, porcelain, and plastics, a need for more specialized cleansing agents arose.

The varied mechanical and chemical resistances of the surfaces to be cleaned and the chemical heterogeneity of the dirt to be removed require a multiplicity of chemical agents, not all of which are compatible with one another. Moreover, cleansing agents that leave no visible residues, produce adequate sudsing, and have pleasant aromas are desired. Finally, the components should be gentle to the skin, they must be regarded as safe from a toxicological standpoint, and the products containing them need to have a long shelf life. In some countries, both the individual components and the cleansing mixtures themselves must be biodegradable. Many types of cleansing agents have emerged to satisfy all of these demands.

Mode of Action. Household cleansing operations are normally carried out at room temperature, primarily because the small amounts of cleansing solution typically employed rapidly acquire the temperature of the surface being cleaned. Dishwashing represents a special case, in which utensils are submerged in a hot solution of the dishwashing agent, whereby they assume approximately the temperature of the bath. These higher temperatures simplify the cleansing operation both by melting grease residues and by accelerating physicochemical and purely chemical processes.

Modern cleansing agents consist largely of surfactants and sequestering agents; hence, their primary action is physicochemical in nature. Strictly chemical phenomena (such as the

Colorant/perfume	present	present	present

saponification of fats or the degradation of starches and proteins) are of lesser significance. The chelating properties of the polymeric phosphates, citrates, or other sequestering agents that are present is of considerable importance, however, in that their ability to remove calcium and magnesium ions reduces the extent to which dirty residues adhere, making them easier to remove.

The primary steps in cleansing are adsorption phenomena occurring at liquid – vapor, liquid – liquid, and liquid – solid phase boundaries. Surfactant adsorption occurs in a nonspecific fashion at all interfaces, whereas that of sequestering agents is specific to polar solids. Surfactant adsorption leads to a reduction in interfacial tension, which allows for improved wetting of solids and, if oily residues are present on the surface, displacement of the oils by roll-up or by micelle formation. The removal of pigmented soils is eased by the fact that when surfactants or sequestering agents are adsorbed at a liquid – solid boundary, they increase the surface potential of both the substrate and the soil, which increases their mutual electrostatic repulsion. As a result, the dirt particles are readily removed from the surface and enter the cleansing solution, where they remain well dispersed [1–3].

1.1. All-Purpose Cleansers

All-purpose cleansers have a wide range of applicability. Their composition is such that they are compatible with any household or commercial surface amenable to wet treatment. Originally, most all-purpose cleansers were in powdered form and contained soda. More recently, however, liquid agents have gained wide popularity. These contain mixtures of anionic surfactants, nonionic surfactants, polymeric phosphates or other sequestering agents, solvents, hydrotropic substances, polymeric compounds, corrosion inhibitors, skin protective agents, perfumes, and colorants. Typical formulations are given in Table 1.

All-purpose cleansers are normally applied as dilute aqueous solutions containing ca. 10 – 15 g of liquid or 2 – 4 g of powdered cleansing agent per liter. The soiled object is wiped with a cloth that has been wrung out after being dipped in the cleansing solution. All-purpose cleansers can also be used in undiluted form to attack heavier dirt layers. The latter procedure requires a subsequent water rinse to prevent visible residues of the cleaner.

All-purpose cleansers are effective with most common kinds of dirt. Their dilute solutions are neutral or weakly alkaline, and are safe for use on most surfaces.

Trade names: Mr. Clean (Procter & Gamble), Ajax (Colgate Palmolive), Dor (Henkel), Magic Clean (KAO).

Surface compatibility is, however, somewhat restricted for the more strongly alkaline powdered cleansers, which are based on formulations of soda and surfactants. Many paints, for example, are sensitive to alkali. Alkaline powders are best suited to the removal of the large quantities of grease commonly encountered in meat markets or commercial kitchens. A typical composition for such a material is:

5 – 25 wt %	anionic surfactant
0 – 5 wt %	nonionic surfactant
10 – 25 wt %	trisodium orthophosphate [*7601-54-9*]
0 – 50 wt %	sodium carbonate [*497-19-8*]
0 – 0.5 wt %	colorant and perfume
	Balance sodium sulfate

Liquid all-purpose cleansers that contain water-soluble organic solvents more effectively remove large amounts of oily or fatty soil, fresh paint, or other colored material than cleaners without solvents. Appropriate additives include glycol ethers and higher molecular mass alcohols. The proper choice of amount and type of solvent can improve cleansing without causing a loss of surface protection.

Trade names: Der Generalreiniger (Henkel).

All-purpose cleansers can be supplemented with antimicrobial agents to confer microbistatic or microbicidal properties. Disinfecting all-purpose cleansers have long been in household use in the United States and in South America, although they have only recently begun to have an impact in Europe. Typical active disinfectant ingredients include quaternary ammonium compounds, phenol derivatives, terpene alcohols (pine oil), aldehydes, and aldehyde – amine condensation products [4].

Trade names: Lysol (Lehn & Fink), Pine Sol (American Cyanamid), Pinho Sol (American Cyanamid, Brazil).

Spray cleansers and foam cleansers are alternative forms of application for liquid all-purpose cleansing agents. The solutions are supplied in containers either equipped with pump-type sprayers or pressurized with a propellant gas. In the latter case, the product is dispensed on the surface as a foam. Some degree of retention on vertical surfaces results, thereby prolonging the time available for action. The major advantage of spray and foam cleansers is their convenience.

Trade name: Formula 409 (Clorox).

1.2. Scouring Cleansers

Scouring cleansers are used to remove particularly stubborn or burned-on dirt from surfaces resistant to the effects of mechanical action. Cleansing results largely from mechanical abrasion by finely divided mineral powder, although active ingredients such as surfactants, sequestering agents, or alkaline salts play a supportive role. Quartz and marble powder, less often diatomaceous earth (kieselgur), pumice, or corundum, serve as the basis of these products. To prevent scratching of surfaces, the mineral powders must be ground to a particle size of less than 0.15 mm. Particle size must be as uniform as possible and larger particles must be absent.

Trade names: Comet (Procter & Gamble), Ajax (Colgate Palmolive), ATA (Henkel), Supa Homing (KAO).

A distinction is made between bleaching and nonbleaching scouring powders. The bleaching agents most often used are organic compounds that decompose to liberate hypochlorite, thereby also conferring disinfectant properties. Examples include sodium dichloroisocyanurate [*2893-78-9*] and trichloroisocyanuric acid [*87-90-1*], as well as the hydrated double salt of sodium hypochlorite and trisodium orthophosphate ("chlorinated orthophosphate") [*56802-99-4*]. Scouring powders containing oxygen bleaches, such as magnesium perphthalate [*93094-22-5*], may also be prepared. These have more pleasant odors than the chlorine compounds.

Liquid scouring agents can be prepared with the same characteristics as powders and are more convenient to use. Since consumers tend to employ liquid scouring agents on more sensitive surfaces, most of the products currently marketed contain the softer abrasive marble dust. Products of this kind will not scratch enamel, tile, or melamine laminate (Formica) counter tops. Examples of typical scouring cleanser formulations are given in Table 2 (see next page).

Trade names: Soft Scrub (Clorox), Viss, Cif (Unilever), ATA (Henkel), Liquid Homing Tough (KAO).

Safety and Handling. Personnel working with powdered quartz must be protected from inhaling the dust by appropriate air filtration equipment because particles smaller than 0.5 μm can cause silicosis. Maximal exposure values (MAK or TLV values) to dust containing quartz have been established in a number of countries. These values are approximately 0.15 mg/m^3 [5]. Scouring agents containing quartz powder are filled by using completely isolated filling machines operating under a slight negative pressure.

Storage. Liquid scouring agents contain 25 – 50 % mineral powder with a relative density more than twice that of the carrier liquid. Proper choice of thickeners and stabilizers permits the preparation of metastable suspensions with an

Table 2. Partial compositions for three types of scouring cleansers

Component	Type of cleanser		
	Powdered scouring cleanser containing bleach *	Powdered scouring cleanser not containing bleach *	Liquid scouring cleanser **

* The powdered cleansers use a quartz powder matrix.
** The liquid cleanser has a water matrix.

adequate shelf life for most purposes (about one year). The required high viscosity of the liquid phase is achieved either by a combination of anionic and nonionic surfactants [6] or with polymeric thickeners such as sodium polymethacrylate or acrylic acid – methacrylic acid copolymers [7].

Quality Control. Quality control of scouring agents primarily entails measuring particle size and particle-size distribution by sieving and measurement of settling times (elutriation).

1.3. Dishwashing Agents

1.3.1. Manual Dishwashing Detergents

Manual dishwashing detergents (MDDs) are everyday products used worldwide for cleaning used dishes, cups, glasses, and pots. The superior performance and acceptance of this product group is due to the liquid formulation of MDDs. Liquid dishwashing detergents are easy to use and offer very good fat and stain removal.

In Europe manual dishwashing detergents are available in classical and in concentrated formulations, for example, under the trade names Palmolive (Colgate Palmolive), Pril (Henkel KGaA), Fairy (Procter & Gamble), and various no-name products of supplier chains.

1.3.1.1. Classical Dishwashing Detergents

The largest product group on the market are the classical manual dishwashing detergents. These products are manufactured with special surfactant combinations and contain roughly 15 % active material. The main ingredients are surfactants, water, perfume, preservatives, and colorants. Formulation ranges for classical MDDs follow:

Anionic surfactant	8 – 12 %
Cosurfactant	1 – 4 %
Dyes, fragrance, preservatives, hydrotropic agents, salt	
Water to 100 %	

A mixture of two to four surfactants is used. The workhorse surfactant is linear alkylbenzenesulfonate (LAS), which offers very good fat removal and a good foam profile. This petrochemical surfactant has a natural counterpart: fatty alcohol ether sulfate (FES). For high-performance MDDs, FES is the preferred surfactant [38], [39]. The type mostly used in MDDs is based on coconut alcohol ($C_{12} - C_{14}$) with two moles of ethylene oxide (EO) (Table 3; see next page). Another widely used basic surfactant is SAS (secondary alkyl sulfonate), which offers good cleaning performance with reduced amounts of hydrotropes [40]. Hydrotropic additives such as urea, cumenesulfonate, or xylenesulfonate help to eliminate turbidity in solution. The performance of anionic surfactants is boosted by adding cosurfactants.

One of the most widely used tests of the performance of MDDs is the plate test. Plates are soiled with different kinds of fats/protein, aged for a defined time, and washed in an apparatus. Evaluators count the number of washed plates until the foam dies down [41].

Table 3. Anionic surfactants for MDDs

Surfactant (abbreviation)	Formula	Trade name	Producer
Linear alkyl sulfonate (LAS)		Marlon	Condea
Fatty alcohol ether sulfate (FES)		Texapon	Cognis
Secondary alkyl sulfonate (SAS)		Hostapur	Clariant

1.3.1.2. Dishwashing Concentrates

During the few last years consumer habits have changed. Today's consumer prefers concentrated products with a high content of surfactants and reduced amounts of water. Concentrates are packed in small bottles, typically 500 mL. These highly concentrated products have excellent cleaning performance. In some formulas up to five different surfactants are combined. Formulation ranges for MDD concentrates follow:

Anionic surfactant	20 – 35 %
Cosurfactant	2 – 10 %
Betaine	
APG/NMG	
Amine oxide	
Nonionic surfactant	0 – 4 %
Ethanol	2 – 7 %
Cumenesulfonate/hydrotropes (optional)	
Dye, fragrance, salts	
Water to 100 %	

The optimum cleaning performance is related to the combination of basic surfactant (anionic) and cosurfactants. Different cosurfactants with special performance profiles are used (Table 4).

Cosurfactants increase the foam profile. Consumers perceive a high-foaming product as having better fat removal. Since concentrated MDDs contain large amounts of surfactants, it is necessary to stabilize the formulation to avoid

Table 4. Cosurfactants for MDDs

Cosurfactant (abbreviation)	Formula	Trade name	Manufacturer
Coco amido propyl betaine (CAPB)		Tego Betain	Goldschmidt
Alkylpolyglucoside (APG)		Glucopon	Henkel/Cognis
N-methylglucamide (NMG)		*N*-methylglucyamide	Clariant
Amine oxide (AO)		Rewominox	Rewo

phase separation. Ethanol or other solvents like glycerin and polyglycols are helpful but reduce the viscosity of the product. Consumers associate the viscosity with performance: high viscosity indicates high performance [42]. Cosurfactants do not reduce the viscosity as much as solvents and are surface-active. Another benefit of cosurfactants is mildness to the skin [43–45]. One of the preferred cosurfactants is coco amido propyl betaine (CAPB) [46–48], often in combination with APG.

1.3.1.3. Skin-Friendly Products

In general MDDs are neutrally formulated with a pH range of 5 – 8 [46]. There is only a minor tendency to irritate the skin, because MDDs are used in very low concentrations (e.g., 2 mL of product in 5000 mL of water). Consumers with sensitive skin or skin problems prefer to use mild products. To minimize skin attack softening ingredients like Lamesoft (protein hydrolysate), refatting agents like fatty acid amides, APG (alkyl polyglucosides), aloe vera, and/or panthenol are added to the basic formulation. Dyes and perfume are eliminated or reduced to a very small amount. Formulation ranges for skin-friendly MDDs follow:

Anionic surfactant	10 – 20 %
Betaine	5 – 10 %
Nonionic surfactant	0 – 20 %
APG	0 – 10 %
Ethanol	2 – 5 %
Aloe vera, panthenol, protein hydrolysate	
Small amounts of dye, fragrance	
Water to 100 %	

Some manufactures use large amounts of nonionic surfactants (FAEO with a particular alkyl chain length and a special degree of ethoxylation). Another way to provide a skin-friendly formulation is the use of APG. The alkyl polyglycoside containing product has the best skin compatibility of tested products (Fig. 1). A standard test design is the patch test. A dermatologist evaluates the degree of changes in the skin according to various criteria. A low irritation score (sum of erythema, edema, squamation, and fissures) indicates excellent skin compatibility.

Figure 1. Results of patch tests on different skin-friendly MDDs

A) Brand claiming good skin compatability; B) Market product for sensitive skin; C) Market product for sensitive skin with APG

1.3.1.4. Liquids with Antibacterial Action

This new group of 2-in-1 products is based on consumer habits in Europe. Today consumers want products with an excellent performance profile and additional benefits like easy dosing. Therefore, it is important to optimize the packaging and the formulation. Henkel introduced Pril 2-in-1 in late 1999. This product is a combination of an MDD and a handsoap with an antibacterial action. It is very convenient to use this product for both doing the dishes and washing the hands. The package design is optimized for this application by using a pump dispenser. Consumers are able to dose the product easy and exactly. The formulation includes an antibacterial component which is tested according to EN 1276, the European standard determing the biocidal activity of ingredients in a formulation against microorganisms. Common microorganism in household areas include *Staphylococcus aureus* (ATCC 6538), *Escherichia coli* (ATCC 10536), *Pseudomonas aeruginosa* (ATCC 15442), and *Salmonella typhimurium* (ATCC 13311). Optimized formulations offer a reduction in live microorganism numbers by five orders of magnitude after 5 min

at room temperature. Formulation ranges for 2-in-1 MDD & handsoap follow:

Anionic surfactant	20 – 40 %
Betaine	2 – 10 %
APG	2 – 10 %
Ethanol	4 – 10 %
Na benzoate, benzoic acid Dye, fragrance	1 – 4 %
Water to 100 %	

1.3.1.5. Dishwashing Habits

Different countries have different cultures, and consumers use manual dishwashing detergents in different ways. In northern European countries such as the Netherlands and Germany, consumers prefer to fill the sink in the kitchen with (hot) water and add the MDD. They use about 5 – 8 L of water and add ca. 2 mL of concentrated or 4 mL of classical products. In southern countries such as Italy and Spain consumers use MDDs on a sponge under running tap water, mainly cold water. During cleaning they apply concentrated product to the sponge or other cleaning devices.

1.3.2. Automatic Dishwashing Detergents

Automatic dishwashing detergents (ADDs) are one of the fastest growing segments of the market for home-care products. The performance of the dishwashers and detergents has reached a high technical standard. Especially cleaners have become a field of high dynamics and innovation. The success of ADDs reflects the desire of consumers for maximum convenience. The product system for automatic dishwashing consists of cleaners, rinse aids, and regeneration salt, reflecting the construction of the dishwasher and the different tasks of the dishwashing process.

1.3.2.1. Dishwashers

Since 1990 automatic dishwashers have become one of the most important appliances in modern households in Western Europe and the United States, with penetration rates up to 60 %. With an average distribution in the EU of 36 % in 1999 the growth potential is still high. On the international market, the most important manufacturers of automatic dishwashing machines are: Brandt Group, BSH, Candy, Electrolux, General Electric, Maytag, Merloni, Miele, and Whirlpool.

Three sizes of dishwashers are available in Europe: normal 60-cm-wide machines (50 cm in Switzerland) with capacities of 12 – 14 international place settings, narrow 45-cm machines for 7 or 8 settings, and table-top ma-

Table 5. Wash temperature and water and energy consumption in modern dishwasher programs

Program	Wash temp., °C	Rinse temp., °C	Water consumption, L	Energy consumption, kWh
Normal/universal	50 – 65	50 – 70	15 – 22	1.0 – 1.5
Strong	65 – 75	65 – 70	18 – 25	1.4 – 1.8
Special/energy-saving	35 – 55	50 – 60	10 – 18	0.6 – 1.3

chines for 4 or 5 place settings. Dishwasher suppliers normally offer different models with up to 10 washing programs. These programs can roughly be classified as normal/universal, intensive/heavy/pots & pans, and special energy-saving low-temperature programs such as eco/delicate/rapid/economy/glass, etc. Wash and rinse temperatures as well as water and energy consumption of the three main program types in modern type dishwashers are presented in Table 5 (see above).

The functionality of an automatic dishwasher is shown in Figure 2 (see previous page) [49].

A typical normal wash program consists of four water fills, as shown in Figure 3.

Figure 3. Normal wash program

After a cold prewash step, the detergent is automatically added at the beginning of the main wash by a special dispensing device, located in the front door of the machine. The dispenser also includes a rinse-aid unit with storage tank and injection system, which automatically adds the appropriate amount of rinse aid when a temperature of about 50 °C is reached in the rinsing step. According to the water quality used in the dishwasher (e.g., residual hardness), the volume of rinse aid can be adjusted by a mechanical switch and amounts to 1 – 6 mL.

In contrast to the United States, most European dishwashers (except in Scandinavia) are equipped with a softening device, in which the incoming water is softened by ion exchange. Depending on the type of dishwasher the ion exchanger is regenerated by addition of NaCl solution for about 20 min, either during the cleaning or final rinse step. After flushing the ion exchange resin with fresh water, the system is ready for a new wash program. Modern dishwashers are commonly equipped with signal lights on the front panel to indicate the the need for regeneration-salt and rinse-aid refill.

In principle, dishwashers can be operated with cold or hot water supply. In the USA, dishwashers are recommended for use with hot water (ca. 50 °C). Therefore, the electric heating capacity of about 1.0 – 1.5 kW is lower than that of European dishwashers (2.0 – 3.0 kW).

In modern dishwashers the traditional electric heating rods at the bottom of the interior are replaced by through-flow heating pipes. Consequently, the final drying process can no longer be supported by additional dry heating. For better drying efficiency, some dishwashers use instead an electric fan or a heat exchanger at the rear of the machine.

The developments in dishwasher technology in the late 1990s were driven by the need to save energy and water to meet European legislation. As with other household appliances automatic dishwashers have to carry an Energy Label [50], [51] which lists energy and water consumption together with cleaning and drying performance. To reach the goal of decreased energy and water consumption at sufficiently high cleaning performance [52], wash temperatures in the normal programs have been decreased from 65 to 55 °C, accompanied by the development of special technologies such as soil-sensor-controlled automatic programs, fuzzy logic control, half-load programs, variation between upper and lower spray level, pulsation spraying, and hardness-controlled regeneration systems and the introduction of new electronically controlled dishwashers.

1.3.2.2. Cleaners

Parallel to the increase in dishwasher penetration in households the European ADD cleaner market has doubled in value since ca.1990.

The main step in the development of cleaner formulations was the change from classical high-alkali cleaners to the new generation of the lower alkali cleaners in the early 1990s. The low-alkali system served as the chemical basis for the develoment of compact ADD cleaners [53].

The *classical system* was based on phosphate (preferably pentasodium triphosphate, $Na_5P_3O_{10}$) as complexing agent for the calcium and magnesium ions in the wash liquor to avoid scale formation. Metasilicate (disodium dihydrogensilicate, $Na_2H_2SiO_4$) was used as a highly alkaline component to soak and remove the dirt from the dishes [54].

Classical cleaners containing metasilicate (pH of wash > 12) must be labeled as corrosive according to the EC formulation guideline. In addition, usually an active chlorine carrier (e.g., trichloroisocyanuric acid) was used as bleach. Today, only 1 – 2 % of ADD cleaners in Europe still contain chlorine bleach.

The development of the *new cleaner generation* can be divided into two main steps. In the first step chlorine bleach was substituted by active oxygen bleach. Oxygen bleach in current ADD cleaners contains peroxo salts such as sodium peroxoborate or sodium peroxocarbonate. Usually bleach activators such as tetraacetylethylenediamine (TAED) are added to enhance the bleaching action. Metasilicate as alkaline carrier was replaced by sodium carbonate, in combination with sodium hydrogencarbonate or less alkaline silicates such as disilicate (tetrasodium silicate). In some products phosphate was substituted by citrate (preferably trisodium citrate dihydrate) and partially complemented by polycarboxylates (e.g., acrylic acid – maleic acid copolymer, sodium salt) and/or phosphonates (e.g., 1-hydroxyethylidene 1,1-diphosphonic acid) to more complex builder systems. In addition, enzymes (e.g., α-amylases and savinases) were incorporated in ADD formulations to increase the cleaning performance against starch- and protein-containing soils under at lower pH (wash liquor pH 9 – 11) [55].

In the second step, since the mid-1990s, phosphate was re-introduced as the main builder component, replacing citrate. Due to its high complexing power phosphate is not only very efficient in scale inhibition but also helps in removing stains that contain calcium and magnesium (e.g., tea stains). Furthermore, phosphate helps to disperse soil particles in the liquor. From the ecological point of view the use of phosphate for ADD seems acceptable at present, since the relative contribution to the overall environmental phosphate input is quite low [56]. However, there are some regulations for maximum phosphorus content of ADD formulas or with respect to the dosage, e.g., in Italy, Switzerland, and the USA.

In the field of active oxygen bleach specific metal complexes (e.g., pentaammineacetatocobalt(III) nitrate and 1,4,7-trimethyl-1,4,7-triazacyclononanmanganese(IV) [Mn_3(TACN)] were identified that can equal or even exceed the action of conventional bleach activators (TAED) especially at lower temperatures of 40 – 55 °C. Today metal catalysts are used in some compact ADD cleaners. In the field of enzymes, changing amino acid sequences by genetic engineering led to amylases and proteases having better compatibility with bleach components and improved performance profiles.

In addition, the compact cleaners usually contain low-foaming nonionic surfactants such as addition products of ethylene oxide with fatty alcohols and silver-protection agents such as 1*H*-1,2,3-benzotriazole [57]. Due to their lower alkalinity and depending on the amount of irritant components (e.g., disilicates) the compact cleaners are either not labeled at all or labeled as irritant.

Table 6 (see next page) lists examples of ADD formulations.

ADD cleaner products can be divided into three basic types: liquids, powder, and tablets.

Liquids were introduced in Germany as early as 1987 but no longer play any role. In some European countries, e.g., France and Great Britain, they still have some importance. Overall they have lost market relevance year by year. Liquids suffer mainly from their low content of active ingredients and chemical and/or rheological instability. These negative aspects outweigh positive aspects like good solubility. Liq-

Table 6. Percentage ADD cleaner formulations (examples)

Ingredient	Classic	Liquid	Compact Step 1		Step 2
	High-alkali	High-alkali	Low-alkali	No label	Low-alkali

Water (balance)	–	55	+	+	+

uid cleaners are mostly based on classical formulations. Up to now all efforts to establish powerful and successful liquid or so-called gel products of the new-generation formula with enzymes and active oxygen bleach on the market failed due to compatibility problems.

Powders were the first ADD products in Europe (1960) and clearly dominated the market until the mid-1990s. Then, in parallel to the rise of the tablets, they constantly lost market shares. However, in contrast to the liquids powders still are of some importance in the market (< 30 % share of market value in 2000). Today the existing powder products in the European market reflect all stages of development. Although the relative importance of the classical products has been decreasing over the years, compact powders gained only limited importance in Europe, except in Germany, Austria, and the Netherlands. As chemical basis for the noncompact powder segment, metasilicate formulations were mostly replaced by "diluted" low-alkali formulations ("traditional powders"). They usually have low contents of oxygen bleach and enzymes and contain certain amounts of, e.g., sodium sulfate as filler. Often part of the components of modern powder products are colored with bleachable dyes to obtain speckles.

Recently, a so-called 2-in-1 powder variety appeared on the market. Compared to the standard powder type it contains a high amount of rinse-aid surfactant, thereby combining cleaning and rinsing properties in a single product.

Powders are always dosed in the dosage chamber of the dishwasher to act in the main-wash cycle. The recommended amount of powder detergent in the wash varies from 20 to 30 g for compact powders and from 40 g to complete filling of the dosage chamber for noncompact powders, depending on soil load and water hardness.

ADD powders are usually based on powdered and granular components and are made by mixing or by special agglomeration processes [58]. Today powders are mainly packed in flexible plastic bags with gussets in composite packaging material. Refill bags are able to stand upright for transport and use. Plastic bottles and folding cardboard boxes are also used.

Tablets were first introduced with a classical formulation (1990, Germany) and since then constantly gained importance. In Europe they are now the dominant ADD type, approaching a total market share of ca. 70 % in 2001. Modern ADD tablets are mainly based on low-alkali compact formulas with phosphate or, to a lesser extent, citrate.

In contrast to powders tablets can in principle be dosed in the prewash or in the main-wash cycle. In the cold prewash the tablet is partially dissolved to start soaking and partially removing soil from the dishes. For example, classical tablets of 30 g weight releasing highly alkaline metasilicate used to work like this.

Tablets with compact formulas are nowadays loaded into the dosage chamber where they re-

lease all ingredients in the main-wash. The currently available enzymes and the active oxygen bleach require certain temperatures for optimal action. Due to the dosage chamber dimensions compact tablets have maximum weights of 25 g.

Tablets are still are the most innovative field in ADD development. The increasing consumer acceptance due to convenience was further promoted by introduction of novel two-phase tablets in the mid-1990s. Today there are various two- and, since 1999, even three-phase tablets with different structures on the EU market. The structures range from parallel layers to corelike.

Phase separation allows possible negative interactions of potentially less compatible components (e.g., bleach and enzymes) to be avoided, thus leading to improved storage stability. Furthermore, phase separation in combination with different dissolution profiles strongly increases the possibility of time-delayed release of specific ingredients relative to one-phase tablets. For example, two-phase tablets are on the market that provide for controlled and separate release of enzymes and bleach, respectively, during the main-wash cycle.

The current state of the art are multiphase 2-in-1 and even 3-in-1 tablets that combine several ADD system components in a single product. The 2-in-1 tablets were introduced in 1999 and combine cleaning and rinse-aid properties. Compared to standard tablets they contain a significantly increased amount of rinse-aid surfactant (up to ca. 10 %), that is distributed in the tablet phases in different ways. Depending on their specific adsorption characteristics the surfactants are partially transferred from the main-wash to the intermediate and the rinse cycles, respectively. In some cases the 2-in-1 tablets contain special rinse-aid phases (e.g., cores) in which the surfactants are processed in a solid, but water-soluble or dispersible matrix. In addition the matrix and/or further core coatings may exhibit controlled-release effects that exploit the change in various physical or chemical parameters on the transition from the main-wash to the subsequent cycles.

The 3-in-1 tablets were introduced in 2001 and combine cleaning and rinse-aid properties and, in addition, contain so-called regeneration-salt substitutes (see Section 1.3.2.4). They exhibit all features of 2-in-1 tablets, as described above, but contain special builder/cobuilder ingredients to cope with tap water hardness. With 3-in-1 tablets the detergent manufacturers claim that there is no need for water softening by the ion exchanger up to certain limiting water hardnesses, (e.g., 21 °d = 3.8 mmol CaO/L). The binding and/or dispersal of the water hardness occurs by means of phosphate and/or polymers, thereby avoiding residues on glass, china, and the dishwasher interior [59].

ADW tabs are manufacured by using a tableting process. A main prerequisite for this technology is the preparation of a free-flowing powder premix. A suitable process unit is, e.g., a batch or continuous granulation step in which powdered or liquid ingredients are mixed to form granules. Afterwards the premix is conditioned by drying, cooling, and sieving and is then finished by postaddition of further specific raw materials or compounds (e.g., enzymes, TAED). The powder premix is fed into a standard tablet press to form the required tablets. Special multistage presses are equipped with two or more dosing and pressing devices to produce multilayer tablets [60–62].

Usually the tablets are single-wrapped in a plastic film of orientated polypropylene (OPP) as a protection against moisture and mechanical stress. They are loose packed in reclosable folded cardboard boxes.

Trade names: Somat (Henkel), Calgonit (Benckiser), Fairy (Procter & Gamble), Sun (Unilever).

1.3.2.3. Rinse Aids

Rinse aids have been used from the beginning of automatic dishwashing in private households. Rinse aids are designed to ensure rapid and film-like draining of the wash solution by optimized wetting in the rinse cycle. This supports spotless drying of the relevant surfaces during water evaporation in the heating and drying cycle at the end of the dishwashing process. The use of rinse aid is especially important if the water contains considerable amounts of dissolved salts even after softening by the ion exchanger.

Foaming must be minimized, as for the cleaner, since the rinsing solution must be vigorously circulated. To an extent that strongly depends on the overall conditions, the rinse

aid must cope with hardness, soil, and alkaline cleaner residues from main-wash liquor tranfer.

Rinse-aid formulations have not changed significantly with time. To fulfill the above-mentioned requirements, they contain typically 10 – 20 % of nonionic surfactants, e.g., addition products of ethylene oxide and propylene oxide with fatty alcohols, 3 – 10 % organic acid (in one case up to 35 % citric acid), 3 – 10 % solubilizers (e.g., cumenesulfonate), perfumes, and water.

The recommended dosage is 2 – 6 mL, depending on rinsing water volume and hardness. Conventionally, the rinse aid is dosed via an automatical dispenser in the dishwasher during the rinse cycle. Since 1999 also so-called 2-in-1 tablets (see Section 1.3.2.2) are available. Detergent manufacturers claim that with these tablets a separate (e.g., liquid) rinse aid is no longer neccessary.

1.3.2.4. Regeneration Salt

In contrast to laundering, automatic dishwashing only delivers acceptable cleaning results when soft water is used. Therefore, dishwashers are equipped with softeners based on ion exchange. The ion exchangers, which are based on conventional ion-exchange resins, are regenerated either in every wash program or, in new electronically controlled models that monitor the hardness of the tap water, when the exchange capacity is almost expired. For the regeneration process pure sodium chloride solution is used. Regeneration salts are special grades with low contents of insoluble residues, free from additives such as anticaking agents. The granulometry must also be controlled with little or no dust particles smaller than 0.3 mm to avoid sedimentation or clogging of the regeneration system.

Since 2001 so-called 3-in-1 tablets containing regeneration salt substitutes are also available.

1.3.2.5. Other Products

Due to the attractivity of the ADD market various additives with additional consumer benefit have become established. Whereas pretreatment sprays based on alkaline or amylase solutions did not reach the market, machine-care and machine-deodorizing products gained importance in the few last years.

Machine-care formulations contain mainly 3 – 10 % nonionic surfactants to wet and loosen the soil residues, 10 – 30 % organic acids to dissolve scale, and 5 – 15 % alkohols such as glycerine as care component. Machine-care products can be applied by hand to rubber seals to keep them pliable and dosed automatically in the cleaning cycle by special devices.

Deodorants are designed to overcome unpleasant odors derived from the soil load after when the dishwasher is opened. They consist of hanger devices for the rack and contain perfumes, which are released through appropriate membranes during the washing program.

1.3.2.6. Performance Assessment

Cleaning Performance. The usual methods for cleaning performance tests are EN 50242 [63] and IEC 436 [64]. However, both methods are designed to measure the performance of electric dishwashers. They were developed at a time when the new compact detergents containing enzymes had not yet become established on the market. Consequently, these methods are often incapable of adequately reflecting the complete wash profile of such detergents. It therefore became necessary to develop a new system for a more comprehensive assessment of the wash performance of dishwasher detergents.

In the mid-1990s, under the auspices of the German Industrial Association of the Manufacturers of Toiletries and Detergents [*Industrieverband Körperpflege- und Waschmittel* (IKW)], a new method was created to select forms of soils from existing methods or develop new soils if necessary for determining the wash profile of the detergent [65].

The types of soil can be roughly classified as:

- Colored, bleachable (tea, ketchup, lipstick, etc.)
- Persistant, burnt-in (burnt meat, burnt milk, burnt casseroles, etc.)
- Dried starch-containing (porridge, starchy sauces, pasta, potatoes, etc.)
- Dried proteinaceous (egg yolk, meat, etc.)

The laboratory soil is specially designed to be difficult to remove in order to distinguish between similar formulations.

The cleaning performance is assessed for the different types of soil on a scale ranging from 0 to 100 %. The evaluation of the cleaning performance is either based on visual inspection of washed and unwashed articles or gravimetrically. For the removal of tea stains a hypochlorite-containing classical detergent and a high-phosphate compact detergent display performance advantages compared with a phosphate-free system with conventional bleach activator. Owing to its higher alkalinity the classical formulation would also remove stubborn and burnt-in soil better than the phosphate-free compact product. However, due to the application of enzymes, the newer generations of phosphate-containing and phosphate-free compact detergents exhibit clear performance advantages on starch and proteinacious soils. This indicates that there are differences between the cleaning performance aspects of the classical cleaner and the two types of low-alkali compact detergents.

Material Care. The European draft standard EN 12875 [66], [67] specifies a dynamic, multicycle test method for the determination of the mechanical dishwashing resistance of domestic articles. This method is also recommended to differentiating between different dishwashing detergents.

With regard to their corrosion-protection effect compact detergents with a high disilicate content are advantageous for porcelain on-glaze decoration. However, thanks to an improved burning technique and the use of in-glaze and/or sub-glaze decorations, sensitive on-glaze decorations are today hardly found in the market. On the other hand, after a few dishwashing programmes cleaners with a high disilicate content cause corrosion phenomena such as iridescence and clouding on glassware (e.g. soda lime glass, potash crystal, and lead crystal glass). Iridescence is caused by the formation of a thin silica layer with different refractive index causing interference patterns which result in a colored appearance.

Permanent clouding, mostly symmetric and ring-shaped, is a further phenomenon that arises from corrosion of glass in automatic dishwashing. The reason for this is the leaching of alkali metal ions due to an uneven temperature distribution in the glass surface during glass production [68]. This occurs, for example, during the smelting process of the top edges or the attachment of stems. Finally, this leads to the conclusion that corrosion protection of delicate on-glaze decorated porcelain can only achieved at the expense of increased glass corrosion.

Additional, glass corrosion is mainly effected by high temperatures ($> 65\,^{\circ}C$) and very low water hardness (< 18 ppm $CaCO_3$) in the dishwashing machine and the composition and manufacturing process of the glass itself.

The phenomenon of silver tarnishing has increased with the introduction of low-alkali compact detergent. The formulation parameters (lower pH, activated oxygen bleach) results in a more sensitive reaction of the silver surface. Additional parameters like higher water hardness, chloride ion concentration, soil, and temperature influence the corrosion behavior as well [69]. Silver tarnishing is prevented by adding agents such as benzotriazole that form an adsorptive layer.

Scale Inhibition. Sufficient complexation of residual water hardness during dishwashing will prevent the formation of insoluble precipitates (e.g., carbonates) on washed dishes and machine parts. Depending on the type of detergent, this is achieved by complexing agents like citrate [55], citrate – phosphate or phosphate, sometimes in combination with phosphonates and cobuilders like polycarboxylates [70].

Evaluation methods [71], [72] are mainly based on visual inspection of the tableware, especially glasses and cutlery, with different rating systems, sometimes also with addition of soil in multicycle tests.

Rinse and Shine Effect. Specific test methods for the evalution of rinse or shine effects depending on various parameters during the dishwash program are described in [73], [74]. As in the scale-inhibition evaluation they are based on visual inspection of tableware, especially glasses and cutlery, on effects like spotting using rating systems, also with addition of soil.

1.4. Floor Cleaners

The all-purpose cleansers described in Section 1.1 are suitable for daily floor cleaning use.

However, strippers are better for cleaning badly soiled floors and removing built-up layers of self-polishing floor wax. These are ammoniacal surfactant preparations containing glycol ethers (e.g., 2-butoxyethanol [*111-76-2*]).

A typical stripper contains 2 – 10 wt % surfactant, 2 – 8 wt % phosphate, 1 – 3 wt % ammonia, 5 – 20 wt % glycol ether, and a perfume in aqueous solution.

Solvent cleaners (mineral spirits) are needed to clean and remove old wax from floors made of moisture-sensitive substrates, such as unsealed wood or parquet. Combination, single-step floor finishes are convenient for routine maintenance of floors. These are products that simultaneously clean and wax. Floor cleaners stress cleaning power, whereas floor polishes are primarily floor finishers (waxes). The cleaners are designed to be added in small quantity to ordinary wash water. They consist of a combination of soap and other detergents, including alkanesulfonates or fatty acid alkanolamides, and they may also contain dispersions of wax or waxlike substances (e.g., montanic acid and montanic acid esters).

A typical floor cleaner contains 10 – 30 wt % potassium soap, 2 – 10 wt % other surfactants, 0 – 6 wt % waxes, and a perfume in aqueous solution.

Floor polishes are self-polishing wax emulsions with a high content of polymeric substances and a smaller amount of surfactants. Products of this type are spread on the floor in undiluted form to produce a thin layer. When dried, they leave a protective film with a high polish. Treated floors can be maintained by regular washing with water that contains a small amount of the same product.

A typical floor polish contains 20 – 40 wt % polymer dispersion (40 %) (e.g., polyacrylate or polystyrene), 2 – 5 wt % surfactant (e.g., fatty alcohol or alkylphenol polyglycol ether), 2 – 6 wt % waxes (e.g., montanic acid esters, polyethylene wax), 1 – 3 wt % plasticizers (e.g., tributoxyethyl phosphate or dimethyl phthalate), 2 – 4 wt % solubilizers (e.g., glycol ethers), a perfume, and some preservatives in aqueous solution.

Quality control tests and standards for floor finishes, floor cleaners, and strippers are, e.g., solids content, solvent content [8–11].

1.5. Carpet Cleaners

Only loose carpets and rugs can be washed or dry cleaned by the techniques employed with other textiles. Rugs can be washed by using gentle, low-sudsing detergents or dry cleaned with organic solvent mixtures. These processes are carried out in very large, dedicated machines. Various techniques are used to clean permanently installed carpets [12], [13]. Carpet sweepers and vacuum cleaners are commonly used to remove loose dust and dirt, but loose rugs are better cleaned by brushing devices. The removal of stubborn, oily dirt requires special cleansing agents. Adhering soil must be loosened from the fibers and transformed into a state that allows its removal by brushing or vacuuming.

Wet processes and dry processes can be distinguished, depending on whether the dirt that has become associated with the cleaning agent is removed immediately along with the cleansing solution (wet process) or after the carpet has been allowed to dry (dry process) [14]. The dry processes are further subdivided into *shampooing* and *powder cleaning,* whereas the usual wet process is known as *spray extraction cleaning* or *steam cleaning.*

Shampooing is accomplished by applying a dilute aqueous solution of carpet cleaner directly to the surface to be cleaned [15]. Typically, a special device containing rotating brushes, which ensure production of a heavy foam and simultaneously work the foam into the carpet, is used. Excess foam is then removed, and after the carpet dries (which may require several days), the dirt-laden cleanser residue is removed by vacuuming. Given its mode of action, a carpet shampoo must be capable of producing a stable foam and leaving behind a dry solid residue that is easily collected. Only a very few surfactants generate sufficient dry residue. Appropriate formulations contain anionic surfactants, such as sodium (C_{15-18})olefinsulfonate [*91082-14-3*], lithium (C_{12-14})alkylsulfate [*90583-20-3*], or sodium (C_{12-16})alkylsulfate [*73296-89-6*], along with such polymers as styrene maleinate resin, polystyrene [*9003-53-6*], polyacrylic resin [*9003-01-4*], or poly(methyl methacrylate) [*9011-14-7*]. The partial composition of a typical carpet shampoo is given, along with the

∗ The two liquid cleaners are aqueous solutions

composition of a spray extraction cleaner and a cleaning powder, in Table 7 (see above).

In the *spray extraction method,* a highly dilute cleansing solution is applied on and into the surface layers of the carpet with special equipment that then removes the wash solution [16]. The carpet fibers are effectively flooded with cleansing agent, and dirt is immediately flushed out of the depths of the pile as a part of the cleaning process. The cleansers contain mixtures of low-sudsing surfactants and sequestering agents in aqueous solution (see Table 7).

Powdered cleansers are especially suitable for home carpet cleaning because their use does not involve any special equipment. *Cleansing powder* is spread over the carpet, brushed in, allowed to collect the dirt, and then removed with an ordinary vacuum cleaner. The powders themselves are easily dispensed preparations of a carrier material, which has been presaturated with an aqueous surfactant solution, occasionally supplemented with alcohol or hydrocarbons. Suitable carriers include sawdust and finely granular preparations of either polyurethane foam or urea – formaldehyde resins (see Table 7).

1.6. Toilet Bowl Cleaners

Toilet bowl cleaners must remove calcium and rust deposits from porcelain surfaces; thus, acidic preparations are effective agents [17]. The most commonly used products are powders that contain sodium hydrogen sulfate [*7664-38-2*] as the major component. They may also contain sodium carbonate [*497-19-8*] or sodium hydrogen carbonate [*144-55-2*], along with small amounts of surfactants such as sodium olefinsulfonate [*91082-14-3*]. The carbon dioxide that is liberated when these products are sprinkled into water serves to agitate the solution and enhance the cleansing action. The partial composition of a typical powdered toilet bowl cleanser, along with the compositions of a liquid cleanser and an alkaline cleanser, is shown in Table 8 (see below).

Liquid bowl cleaners usually contain hydrochloric [*7647-01-0*], phosphoric [*7664-38-2*], or formic acid [*64-18-6*], along with surfactants (see Table 8). The use of a 1 : 4 mixture of sodium alkylbenzenesulfonate and an alkylphenol polyglycol ether containing

∗ The two liquid cleaners are aqueous solutions

ten moles of ethylene oxide has been found to be particularly advantageous.

Alkaline products containing bleach (hypochlorite) are often used for cleaning toilet bowls even though they are not able to remove calcium deposits (see Table 8). Such materials must not be used in combination with acidic products because the evolution of deadly chlorine gas would result.

1.7. Toilet Hygiene and Deodorant Products

Toilet hygiene and deodorant products include disinfectant cakes, tank disinfectant dispensers, and toilet bowl deodorants.

The *deodorant and bowl cakes* are solid surfactant preparations with a high perfume content. These are normally supplied in a plastic holder that can be suspended from the edge of a toilet bowl. Each time the toilet is flushed, the incoming water dissolves a small amount of the cake material, which both cleanses and deodorizes. Deodorant properties are also sometimes conferred by cakes containing *p*-dichlorobenzene [*106-46-7*] (with or without surfactant), although the use of this compound has raised serious ecological questions. The effectiveness of *p*-dichlorobenzene stems from its inherently strong odor and its high vapor pressure. Table 9 (see below) gives the compositions of typical toilet hygiene and deodorant products.

Automatic tank dispensers are highly colored surfactant blocks that are packaged in plastic containers or in a water-soluble film. They are placed directly in the toilet tank to lower the surface tension and color the water used for flushing. The surfactants employed are highly foaming anionic agents, preferably sodium alkylbenzenesulfonates, and structure-building nonionic compounds, such as highly ethoxylated (> 25 ethylene oxide units) fatty alcohol [*68439-49-6*] or alkylphenol polyglycol ethers [*9016-45-9*]. The solubility of the product is adjusted by adding waxy substances such as stearic acid [*57-11-4*], cetyl alcohol [*36653-82-4*], montanic acid [*68476-03-9*], or montanic acid esters [*73138-46-2*] (see Table 9).

1.8. Drain Cleaners

Drain cleaners are strongly alkaline products designed to unclog the drains and traps of sinks, bathtubs, etc., when these become plugged with hair, grease, food residues, soap deposits, or the gelatinous masses that can result from the action of microorganisms [18].

Powdered drain cleaners are effective partly because their dissolution in water generates heat. A temperature of 90 °C can be achieved by using ca. 25 g/100 mL. Many drain cleaners also contain finely granulated aluminum, which reacts with the hot aqueous alkali to evolve hydrogen gas. Sodium nitrate converts this hydrogen to ammonia. This gas evolution provides mechanical assistance for the removal of residues and deposits.

Liquid drain cleaners are used largely to prevent clogging. The inclusion of substances that release chlorine ensures the decomposition of hair. Compositions of drain cleaners are shown in Table 10.

Drain cleaners in aerosol cans – so-called *pressure cleaners* – are an example of propellant packaging. In the course of their use, a burst of

1.9. Metal Cleaners

Special metal polishes are used to clean such metal surfaces as stainless steel sinks, faucets, metal trim, silverware, etc. These products contain fine abrasives with a particle size $< 20\,\mu m$. Weakly acidic materials containing lactic [*50-21-5*], citric [*77-92-9*], or phosphoric acid [*7664-38-2*] are preferred for cleaning *stainless steel, nickel,* and *chromium.* Fatty alcohol [*68439-49-6*] or alkylphenol polyglycol ethers [*9016-45-9*] with 7 – 12 ethylene oxide units are added as emulsifiers and dispersing agents.

Polishes for the *nonferrous metals* are weakly ammoniacal. The usual dispersing agents are the ammonium salts of oleic [*544-60-5*] or stearic acid [*1002-89-7*]. Chelating agents are often added to enhance cleaning. These include ammonium citrate [*3458-72-8*] and ammonium oxalate [*1113-38-8*]. *Silver* objects can be freed of sulfide tarnish by dipping them in products containing thiourea [*62-56-6*] along with either hydrochloric [*7647-01-0*] or sulfuric acid [*7664-93-9*]. Table 11 shows the compositions of several types of metal cleaners.

1.10. Window Cleaners

Window cleaners must leave no residue on glass surfaces. Such products are composed almost exclusively of liquid with small amounts of necessary surfactants. Two types of window cleaners are available. One comes packaged in a plastic bottle equipped with a sprayer or spray pump and is ready to use. The other, known as window washing concentrate, is a mixture that must be diluted with water before use [19]. The compositions of the two types of window cleaners are shown in Table 12.

Table 12. Partial compositions of window cleaners∗

1.11. Automotive Cleansers

Automotive cleansers must not damage auto paint. They must be freely soluble in and compatible with hard water, be roughly neutral (i.e., pH), and possess effective wetting and cleaning powers. The active detergent in most liquid

car cleaners is comprised of alkylbenzenesulfonates, alkylsulfonates, or fatty alcohol sulfates together with fatty alcohol or alkylphenol polyglycol ethers [20].

Commercial car washes require low-sudsing products with a high content of polyphosphates. These normally leave behind trace residues of hydrophilic cleaning agents. Consequently, washing should always be followed by treatment with a protective agent to return the paint to its normal hydrophobic state. This ensures that water on the surface will gather into droplets and run off. Actual drying is necessary only on horizontal surfaces, and this is accomplished in automatic car washes with the aid of an air stream. The protective agents commonly employed are cationic preparations containing dimethyldistearylammonium chloride [*61789-80-8*] [21].

The compositions of typical automobile-finish cleaners and automobile-finish protective agents are given in Table 13.

∗ These preparations are in aqueous solution

In general, *car windshields* are washed with common window cleaners. Especially stubborn dirt such as silicone films is removed by using a suspension of a mild abrasive such as siliceous chalk or finely dispersed silicic acid in an alcoholic solution containing a wetting agent. To clean the windshield effectively while a vehicle is in motion, wetting agents compatible with hard water are added to the windshield washer reservoir. Appropriate substances include alkyl polyglycol ether sulfates or fatty alcohol polyglycol ethers. For winter use, addition of an antifreeze such as alcohol or some other freezing point depressant is necessary [22–24]. The compositions of windshield washer additives for summer and winter use are shown in Table 14.

Table 14. Partial compositions of windshield washer additives for summer and winter use

Component	Additive for summer use∗	Additive for winter use
Surfactant, wt %	15 – 20	1 – 2
Sequestering agent, wt %	1 – 5	
Ethanol, wt %		78 – 94
Ethylene glycol, wt %		5 – 20

∗ The preparation is used in aqueous solution

Tar removers, surfactant-containing solvent cleaners, are used to remove spots of tar or asphalt. Suitable surfactants include alkylphenol polyglycol ethers having 8 or 9 ethylene oxide units. The product is sprayed or painted on the spot, and then removed with water [25].

A typical tar remover contains 60 – 80 wt % mineral spirits, 15 – 25 wt % perchloroethylene or citrus terpenes, and 5 – 15 wt % surfactants.

1.12. Building Facade Cleaners

Because of the number of materials employed in the facades of buildings and the variability of their resistance to chemicals, any cleansers to be used on them must be thoroughly tested for suitability [26]. Facades made of *acid-resistant masonry* (including brick) are usually treated with strongly acidic cleansers, preferably those containing acids such as hydrofluoric [*7664-39-3*] or phosphoric acid [*7664-38-2*] that form sparingly soluble calcium salts. A typical such cleanser contains 10 – 20 wt % hydrofluoric acid, 10 – 20 wt % phosphoric acid, and 5 – 15 wt % surfactants in aqueous solution.

Acid-sensitive materials, such as concrete or plaster, require the use of strongly alkaline media. Alkaline treatment must be followed by neutralization with dilute acid to prevent possible subsequent efflorescence. A typical such alkaline cleanser contains 10 – 30 wt % sodium hydroxide and 1 – 4 wt % thickener (e.g., polyacrylic acid) in an aqueous solution.

Stainless steel facades are cleaned with mineral spirit – mineral oil emulsions. Heavily soiled or weathered objects require the use of either emulsions containing abrasives or weakly acidic cleansers containing 20 – 40 wt % phosphoric acid and 5 – 15 wt % surfactants in an aqueous medium. Such emulsions with abrasives typically contain 15 – 25 wt % mineral oil,

15 – 25 wt % mineral spirits, 5 – 10 wt % emulsifiers, and 10 –20 wt % abrasive (e.g., Neuburger siliceous chalk or diatomaceous earth) in an aqueous solution. *Anodized aluminum*[27] facades are cleaned with mineral spirit – mineral oil emulsions, although special acidic cleaners containing nitric acid [*7697-36-2*] [28], [29], or fluorosilicic acid [*16961-83-4*] can also be used [30], [31]. Mineral spirit – mineral oil emulsions typically contain 20 – 30 wt % mineral oil, 20 – 30 wt % mineral spirits, and 5 – 10 wt % emulsifiers in an aqueous solution.

2. Cleansers and Disinfectants for Use in the Food Industry

All surfaces that come in contact with foodstuffs during their manufacture, processing, or transport must undergo cleansing at prescribed intervals. The various branches of the food industry (e.g., beverage and canned goods manufacturers and the sugar, dairy, meat, and fats industries) are susceptible to different kinds of contamination; thus, cleansing in this context necessitates the availability of a wide variety of different chemical agents. Specific bacteriological concerns must also be addressed. Most can be satisfied only by a special disinfectant treatment, either subsequent to or as a part of the cleaning process. Numerous special disinfectants have been developed, and combination agents that contain mixtures of detergents and disinfectants are available.

2.1. Cleansers

Cleansing agents must be capable of removing contaminants containing proteins, fats, carbohydrates, and certain inorganic contaminants. The corresponding products are invariably mixtures of several components and are supplied as concentrated powders or liquids, less commonly as pastes; these are to be diluted with water to final concentrations of 0.5 – 2 wt % (0.05 –0.5 wt % for disinfecting agents). Such products must not corrode the various treated surfaces. They must dissolve readily and show a limited foaming tendency in largely automatic processes; they must also prevent the deposition that might otherwise result from hard water.

Decontaminators. The primary decontaminators usually are alkaline. These include sodium or potassium hydroxide, sodium or potassium carbonate, alkali-metal salts of orthophosphoric acid and organic acids, and sodium and potassium water glasses having silicon dioxide to alkali-metal oxide ratios of 0.7 – 3.3 [32].

Inorganic acids, such as sulfuric, nitric, and phosphoric acids, are used to remove largely inorganic contaminants such as milk or beer scale [33]. Hydrochloric and hydrofluoric acids are employed only in exceptional cases, such as in cleansers for masonry floors.

Sequestering Agents ("Builders"). A number of suitable organic and inorganic sequestering agents have been employed to complex the calcium and magnesium ions present in water and, thereby, prevent the formation of incrustations or deposits on boundary surfaces [34]. These substances also aid in the cleansing operation by breaking up soil lattices. The alkali-metal salts of the oligophosphoric acids, diphosphates, triphosphates, tetraphosphates, and more highly condensed phosphates (e.g., hexametaphosphate) remain the most important inorganic sequestering agents, but their hypertrophic effects on streams are a serious environmental concern.

Unlike phosphate, organic sequestering agents are not decomposed by hard industrial waters, and they are useful for alkaline and high-temperature applications. Nitrilotriacetic acid (NTA), ethylenediaminetetraacetic acid (EDTA), gluconic and polyacrylic acids and their alkali-metal salts, and phosphonic acid or phosphonates are examples of such organic sequestering agents. Both organic and inorganic sequestering agents usually perform several functions. They serve simultaneously as alkaline soil removers, as dispersants, and as water softeners and are among the most important cleanser ingredients.

Surface Active Agents. The removal of greasy dirt requires additional surface active agents [34]. Such anionic surfactants as fatty alcohol sulfates, alkylbenzenesulfonates, and soaps are used. The nonionic polyglycol ethers of fatty alcohols and alkylphenols, the latter syn-

thesized by reaction of the corresponding alcohols with ethylene oxide, are also suitable. The solubility and foaming characteristics of such compounds depend on the degree of ethoxylation. Propylene oxide adducts also find some application, as do alkylamine oxides. Heavily foaming mixtures of these latter surfactant, often in combination with alkaline or acidic cleansing agents, are used in cleansing operations that entail production of stable foams. Such foaming processes are preferred in the meat-cutting and meat-packing industries for external cleansing operations on processing and transport equipment. The stable foam permits the cleansing or disinfecting agent to act over a prolonged period of time.

Corrosion Inhibitors. Light metals such as aluminum and its alloys are attacked more or less vigorously by alkaline and most acidic cleansers [35]. Water glass (sodium silicate) is virtually the only agent used to minimize destructive corrosion under alkaline conditions. A number of inhibitors can be employed in acidic situations. The proper choice depends on the specific material and acidic cleanser. The increasing use of stainless steel is reducing the need for inhibitors. Tin- and zinc-plated utensils and equipment are rarely encountered.

Foam Inhibitors. Foam is a consequence of the normal behavior of components of the cleansing agents, and it can also be produced by certain contaminants, such as those encountered in beverage bottles. Special ethoxylated and propoxylated compounds can be introduced to reduce foaming, as can such water-insoluble materials as paraffin oil and silicones [34], [36]. Ethoxylated – propoxylated block polymers are particularly ideal for cleansing operations because these materials can show decreasing solubility with increasing temperature and thereby increasingly inhibit foaming as the temperature is raised during cleansing. At the low temperatures found in subsequent rinse steps, they regain their solubility and can be rinsed cleanly from the newly washed surfaces.

Dust Inhibitors, Anticaking Agents, and Solubilizers. Products marketed in powdered form often contain compounds that inhibit dust formation, thereby minimizing dust exposure for personnel working with them. Other additives may be needed to prevent caking of the powders. Aqueous products often require the presence of solubilizers, commonly derived from mono- and polyfunctional alcohols.

Enzymes. Enzymes such as proteases and amylases are useful in attacking protein- and starch-containing contaminants. They are particularly valuable for cleaning corrodible objects. An example is the cleaning of membranes employed in apparatus for ultrafiltration (reverse osmosis).

2.2. Disinfectants (→ Disinfectants)

The food industry employs as disinfectants mainly active chlorine compounds, quaternary ammonium salts, ampholyte soaps, iodophors, peroxy derivatives, and certain aldehydes [36]. For disinfection of the hands, various mono- and polyfunctional alcohols are used. Phenolic disinfectants are seldom used in the food processing industry. In addition to their microbiological activity [37], disinfectants must not be corrosive or cause foam, odor, or skin irritation. They may not leave residues on food unless these can be considered absolutely harmless.

Chlorine-Producing Compounds. The disinfectant use of salts of hypochlorous acid, both in powdered and liquid form, continues because they are inexpensive and have a broad spectrum of microbiological activity. Liquid products usually contain alkali-metal hypochlorites. Among powdered materials, the adducts of alkali-metal hypochlorites with trisodium phosphate and also the salts of mono-, di-, and, to some extent, trichlorocyanuric acid are used. Chloramines, such as chloramine-T (→ Chloramines), which form hypochlorites in aqueous solution are also used.

Hypochlorite is also used in combination disinfectant cleansers, which contain ingredients other than the cited alkaline substances to enhance cleansing. Dispersants, wetting agents, and corrosion inhibitors such as silicates are among these additives. Hypochlorite disinfectants typically contain 60 – 70 wt % sodium or potassium hypochlorite, 10 – 20 wt % sodium

or potassium hydroxide, and 3 – 5 wt % pentasodium or pentapotassium triphosphate in an aqueous solution.

Peroxy Derivatives. The common peroxy derivative disinfectants are hydrogen peroxide and peroxyborate, although salts of peroxodisulfuric acid are also occasionally used. Hydrogen peroxide and peroxyborate are noted for their long shelf life, but their disinfecting action is too slow for most purposes. Peroxy derivatives of the lower fatty acids, especially peroxyacetic acid, are more suitable because they display more rapid microbiological effects. Such products are used almost exclusively in acidic to neutral environments and usually contain stabilizers of various types. Both organic peracids and hydrogen peroxide are used in one-step acidic cleansing products.

Iodophors. Disinfectants based on iodine contain high molecular mass substances with surfactant properties, preferably nonionic wetting agents. These are particularly effective dispersants for elemental iodine and thereby promote its dissolution in water. Such disinfectants also contain varying amounts of phosphoric acid, antifoam agents, and corrosion inhibitors. They are usually offered as liquids, although materials in powdered form also exist. A disinfectant of this kind typically contains 10 –40 wt % phosphoric acid, 1 – 3 wt % iodine, 1 – 2 wt % corrosion inhibitor, 0 – 20 wt % isopropyl alcohol, and 1 – 6 wt % ethoxylated – propoxylated block polymer in an aqueous solution.

Quaternary Ammonium Compounds. Salts under this heading are neutral disinfectants that possess surfactant properties. The (C_{12-18})alkylbenzyldimethylammonium chlorides are examples. Various quaternary ammonium compounds are often combined to increase the activity of the product against specific microorganisms. Some quaternary ammonium compounds can be combined with phosphoric or sulfuric acid or with alkaline cleansing agents to yield disinfectants with cleansing properties. A typical quaternary ammonium salt disinfectant contains 5 – 20 wt % (C_{12-18})alkylbenzyldimethylammonium chloride, 5 – 10 wt % (C_{12-18})alkyldichlorobenzyldimethylammonium chloride, 1 – 3 wt % alkyl polyglycol ether, and 0 – 3 wt % ethoxylated – propoxylated block polymer in aqueous solution.

Ampholytes. Ampholytes, ampholytic surfactants, or ampholytic soaps have a betaine structure. They find use as disinfectants, often in combination with related materials or, occasionally, with quaternary ammonium compounds.

Halocarboxylic Acids. Halocarboxylic acids, particularly monochloro-, monobromo-, and monoiodoacetic acids, are used as disinfectants, especially in the beverage industry. The haloacids are supplied in combination with sulfuric or phosphoric acid, or both. Combinations including surfactants, foam inhibitors, sequestering agents, and solubilizers provide one-step disinfectant cleansers. Products based on a halocarboxylic acid are more stable than peroxide- or iodophor-based acidic disinfectant cleansers and, consequently, display a longer active lifetime. Their use in a carbon dioxide atmosphere for the cleansing and disinfecting of fermentation tanks in the brewing industry is particularly noteworthy (→ Beer).

Aldehydes and Alcohols. Only formaldehyde and glutaraldehyde are used as disinfectants to any extent. They are generally supplied in the form of mixtures containing other surfactants. Aqueous alcoholic products, often containing perfumes, are commonly employed for disinfecting the hands.

1. Coal Petrology

1.1. Coal Characterization

Coal is an extremely heterogeneous, complex material that is difficult to characterize. Coal is a rock formed by geological processes and is composed of a number of distinct organic entities (macerals, i.e., the microscopically recognizable individual constituents of organic matter) and lesser amounts of inorganic substances (minerals). Each of the coal macerals and minerals has a unique set of physical and chemical properties; these in turn control the overall behavior of coal. Although much is known about the properties of minerals in coal, for example, the crystal chemistry, crystallography, and magnetic and electrical properties, surprisingly little is known about the chemical and physical properties of individual coal macerals [1]. Even though coal is composed of macerals and minerals, it is not a uniform mixture of these substances. The macerals and minerals occur in distinct associations. These macroscopic association are called lithotypes, and each lithotype has a set of physical and chemical properties that also affect coal behavior.

Coal seams, the basic units in which coal occurs, are in turn composed of layers of coal lithotypes, and individual coal seams may also have their own sets of physical and chemical properties. For example, even if two coal seams have the same average maceral and mineral composition, the seams may have significantly different properties if the maceral associations in lithotypes in the two seams are different. The enclosing rocks immediately adjacent to a coal seam can also affect the properties of the coal. This aspect is particularly important in mine design, production, and strata control. The compositional characterization of a coal seam must cover the nature of the macerals, the lithotypes, the entire seam, and the association of the seam with the neighboring strata.

In addition to compositional factors, coal properties also change with the rank or the degree of coalification of a given sample of coal. Coal is part of a metamorphic series ranging from peat, through lignite and subbituminous and bituminous coal, to anthracite. Temperature, pressure, and time mainly alter the botanical precursors of coal (plant fragments) through this metamorphic series. As the rank of the coal changes, the properties of the coal macerals change progressively and, therefore, so also do the properties of lithotypes and the entire seam.

Because of these factors, coal characterization requires a detailed knowledge of the type (maceral composition), the rank (degree of coalification) and the grade (content of impurities) of the coal. All coal properties are ultimately a function of these three factors.

1.2. The Maceral Concept

The term maceral was introduced by Stopes to distinguish the organic components of coal (macerals) from the inorganic components (minerals) [2]. The term is now interpreted in two conflicting ways. The interpretation of the International Committee for Coal Petrology (ICCP)

is that a maceral is the smallest microscopically recognizable component of coal [3]. This conception, generally held by most coal petrographers all over the world, is based on morphology and other criteria such as size, shape, botanical affinity, and occurrence. The ICCP concept implies that the properties of the macerals change with rank. Thus, the same maceral, vitrinite, can exist in a bituminous coal as well as in an anthracite.

The basis of the petrographic study of coal composition is the idea that coal is composed of a number of distinct macerals. The entire body of coal petrographic literature supports this idea and is in direct contrast to the earlier chemical concept of coal being composed of a single unique molecular substance. Although the concept and the term "coal molecule" may once have been useful, modern chemical studies of coal reveal different molecular frameworks depending on coal's heterogeneous maceral composition and rank.

1.3. Maceral Types and Properties

A large number of macerals have been described in terms of their appearance in reflected light when observed through an oil immersion objective. The Stopes – Heerlen system used by the ICCP is given in part in Table 1. For routine maceral analysis, the conventional subdivision into three maceral groups, i.e., vitrinite, liptinite (formerly called exinite) and inertinite is useful.

As shown in Table 1, coal macerals fall into three distinct groups: vitrinite, liptinite, and inertinite. *Vitrinite macerals* are generally the most abundant, commonly making up 50 to more than 90 % of the Eurameric coals (European and North American coals of Carboniferous age). This group is not as abundant in Permian Gondwana coals that originate in the southern hemisphere.

Most vitrinite macerals are derived from the cell wall material (woody tissue) of plants. Although the details of the complexity of the vitrinization process are not well understood, it is generally believed that during the coalification process the plant cell wall material is chemically altered and broken down into colloidal particles that are later deposited and desiccated. This process commonly homogenizes the components so that the resulting macerals are structureless. The variation in vitrinite macerals is usually thought to be due to differences in the original plant material or to different conditions of alteration at the peat stage or during later coalification.

Table 1. Macerals of hard coal according to the Stopes – Heerlen system (after ICCP 1957, 1963, 1971, 1975, 1985 [3])

Maceral group	Maceral	Submaceral*
Vitrinite	telinite	telinite 1
		telinite 2
	collinite	telocollinite
		gelocollinite
		desmocollinite
		corpocollinite
	vitrodetrinite	
Liptinite	sporinite	
	cutinite	
	resinite	
	alginite	
	liptodetrinite	
Inertinite	micrinite	
	macrinite	
	semifusinite	
	fusinite	pyrofusinite
		degradofusinite
	sclerotinite	fungosclerotinite
	inertodetrinite	

* This category can be arbitrarily extended, if required

Under the microscope, vitrinite macerals have a reflectance (brightness) between that of the liptinite and inertinite macerals. Because the reflectance of the vitrinite macerals shows a more or less uniform increase with coal rank, reflectance measurements for the determination of rank are always taken exclusively on vitrinite submacerals (collinite, telocollinite, desmocollinite). The reflectance of vitrinite macerals is also anisotropic, so that in most orientations a particle of vitrinite will display two maxima and two minima with complete rotation. Vitrinite is almost always the most abundant maceral present and makes up the groundmass in which the various liptinite and inertinite macerals are dispersed. It has a uniform gray color and is always anisotropic. With UV excitation, some vitrinites will fluoresce.

A modernized vitrinite classification and nomenclature system was introduced by the ICCP in 1994 [4]. As shown in Table 2, six vitrinite macerals have been grouped into three subgroups according to their degree of degradation: telovitrinite, detrovitrinite, and gelovitrinite.

Table 2. Subdivision of the group of vitrinites according to the ICCP System 1994

Subgroup	Maceral
Telovitrinite	telinite
	collotelinite[a]
Detrovitrinite	vitrodetrinite
	collodetrinite[b]
Gelovitrinite	corpogelinite[c]
	gelinite[d]

According to ICCP (1963, 1971, 1975, 1985 [3]):
[a] elocollinite;
[b] desmocollinite;
[c] corpocollinite;
[d] gelocollinite

Liptinite macerals are derived from the hydrogen-rich parts of plants, i.e., the spores and pollen, cuticles, resins, and algae. This group generally makes up 5 – 15 vol % of most Carboniferous coals, although it dominates some unusual types of coal such as cannel and boghead. In any given coal, liptinite macerals have the lowest reflectance. Liptinite macerals are the most resistant to alteration or metamorphism in the early stages of coalification; thus, the reflectance changes are slight up to the rank of medium-volatile coal. In this range the reflectance of liptinite macerals increases rapidly until it matches or exceeds the reflectance of vitrinite macerals in the same coal and, thus, essentially disappears. Sporinite is the most common of the liptinite macerals and is derived from the outer waxy cell walls of fossil spores and pollen. It generally has the form of a flattened spheroid with upper and lower hemispheres compressed until they fuse. The outer surfaces of the sporinite macerals often show various kinds of ornamentation. In Paleozoic coals, two sizes of spores are common. The smaller ones, usually $< 150\,\mu m$ in diameter, are called microspores, and the larger ones, ranging up to several millimeters in diameter, are called megaspores. Cutinite, found as a minor component in most coals, is derived from cuticles, which are formed within the outer cell wall of the epidermis of leaves, roots, stems, etc. of plants. It occurs as long stringers, which often have one fairly flat surface and another that is crenulated. Cutinite usually has a reflectance equal to that of sporinite. Occasionally the stringers of cutinite are distorted. Resinite is also common in most coals and usually occurs as ovoid bodies with a reflectance slightly greater than that of sporinite and cutinite but still less than that of vitrinite. Most resinites originate from resins and waxes. Some resinite may appear to be transparent and strongly yellow-fluorescing, at the subbituminous stage of coalification. In some cretaceous and tertiary coals, a number of different forms of resinite may be distinguished by using fluorescent microscopy. Alginite is derived from fossil algae colonies. It is rare in most coals and is often difficult to distinguish from mineral matter. However, under excitation with blue light it fluoresces with a brilliant yellow color and can display a distinctive cauliflower-like appearance.

The *inertinite* maceral groups are mainly derived from the same plant material as the vitrinites, usually woody tissue, that has been strongly altered by charring in a forest fire or by biochemical processes such as composting either before or shortly after deposition. These processes are described as fusinitization. These macerals can make up 5 – 40 % of most Eurameric coals. In southern hemisphere coals of Permian/Triasic age, this group commonly is more abundant than vitrinite. The inertinite macerals have the highest magnitude and greatest range of reflectance of all the macerals. They are distinguished by their relative reflectances and by the presence or absence of cell texture. Fusinite is seen in most coals and has a charcoal-like structure (pyrofusinite). It is always the highest reflecting maceral present and is distinguished by a cell texture that is commonly broken into small shards and fragments. Semifusinite can have the cell texture and general features of fusinite except that it is of lower reflectance. But normally the cell textures of these macerals are poorly preserved. Semifusinite is also the most abundant of the inertinite macerals in most Permian Gondwana coals. Macrinite is a very minor component of most coals and usually occurs as structureless ovoid bodies or as structureless groundmass with the same reflectance as fusinite. Micrinite occurs as very fine granular particles of high reflectance. It is commonly associated with the liptinite macerals and sometimes gives the appearance of actually replacing the liptinite. The genesis of macrinite and micrinite is uncertain or insufficiently understood. Sclerotinite, found as a minor component in most hard coals, has been referred to as fungal remains, but the greater portion of sclerotinite, which is

found in carboniferous and permian bituminous coals originates from cell secretions. The maceral inertodetrinite contains mainly small fragments of fusinite, semifusinite, sclerotinite, and macrinite. It is concentrated in many subaquatic coal. Some southern hemisphere coals contain characteristic concentrations of inertodetrinite.

2. Coalification

A unique and often troublesome feature of coal that distinguishes it from other fuels and bulk commodities is its property of rank. All coal starts out as peat, which is then changed into progressively higher ranks of coal. This transformation is generally divided into two phases. The first, which occurs in the peat stage, is called diagenesis or biochemical coalification. In this phase most of the plant material making up the peat is biochemically broken down. Specifically, most of the cellulose in the plant material is digested away by bacteria and fungi, and the lignin in the plant material is transformed into humic acids and humic compounds, humins. Some plant material is also thermally altered by partial combustion or biochemical charring. Still other plant material, such as spores and pollen, survive the diagenesis stage without much change. After diagenesis is complete and the altered peat is buried, geological forces begin to act in the geological or metamorphic phase of coalification.

Because of the common occurrence of high-rank coals in geologically deformed areas, for example, anthracite in the eastern Appalachian Mountains and low-volatile bituminous coal in the folded and faulted Canadian Rocky Mountains, it was assumed that tectonic pressure was responsible for the high rank of most coals. However, this position has now lost most of its support because studies in the folded coal seams of the Ruhr Basin show that isorank lines (isovols) follow the folds in the seams [5]. This shows that the coal achieved its rank before the structural deformation and was not altered during or after such deformation. Similar studies of stratigraphic relationships in the Canadian Rocky Mountains showed that the higher rank coals correlated with increasing depth of burial and not tectonism [6]. Laboratory experiments using increased confining pressure have not led to increased coalification [7].

The majority of the geological evidence suggests that temperature is the major factor in coalification and that the temperature range in which most coalification takes place is 50–150 °C. The depth at which these temperatures occur is a function of the natural geothermal gradient (dT/dZ), which ranges from 0.8 °C/ 100 m to 4 °C/100 m. Therefore, at these two geothermal gradient extremes, the depth at which 150 °C would be reached, if a surface temperature of 20 °C is assumed, is 16.25 km (53 300 feet, 10.1 miles) for the lowest gradient and 3.25 km (10 700 feet, 2.02 miles) for the highest. The major lines of evidence for the importance of temperature in coalification are as follows:

1) An increase in coal rank and temperature with depth is confirmed by thousands of bore holes.
2) Lines of equal rank contour igneous intrusions and show an increase in rank in the direction of the intrusion. In some cases, natural coke is found at the contact of a coal seam with an intrusion.
3) Laboratory experiments show that wood can be coalified by heating in an inert atmosphere. Increasing the pressure alone has no effect on the coalification of wood.
4) When thermodynamic factors are considered, it is clear that temperature should have more of an effect than pressure. While an increase in temperature will encourage most coalification reactions by increasing the available energy, an increase in pressure may often inhibit such reactions by raising the energy requirements for such reactions to take place. However, pressure changes the physical structure of the coal.

It was long thought that time was not a factor in coalification, and the example of the Russian paper coals of lignite to lower subbituminous rank and Lower Carboniferous age was often cited as evidence. However, it is now believed that if the peat has been buried deeply enough to effect coalification, then time does have a "soaking effect". For example, in Venezuela there is a subbituminous coal of Eocene age that has been buried at a depth of 1120 – 1220 m at 125 °C for $(10-20)\times10^6$ years. In Germany there is a coal that has been at the same depth and temperature for 300×10^6 years and is of anthracite rank [5]. Numerous other examples have been found and a number of correlation charts relating depths of

burial, temperature, rank, and time are based on this type of data.

Changes in the coal rank correspond to changes in most of the properties of the coal. For example, as rank increases, moisture, volatile matter, and ultimate oxygen and hydrogen decrease, whereas fixed and ultimate carbon, calorific value, and reflectance increase. All of these measurements and even some combinations of these have been used as measures of coal rank. However, with the exception of reflectance, they all suffer from two major drawbacks. First, none actually change uniformly across the rank range of coal. Second, they are all bulk properties of coal and, thus, can be significantly affected by changes in maceral composition having nothing to do with rank. For example, a coal with a higher-than-normal content of liptinite macerals can have a higher-than-normal hydrogen content and, therefore, appear to have a lower rank than it actually does on the basis of a rank parameter independent of composition such as reflectance. The reflectance parameter of coal is based on the amount of light reflected from the vitrinite macerals in a coal compared to a calibration standard of known refractive index and reflectance. The vitrinite reflectance of coal changes uniformly across most of the coal rank range. However, it is not very sensitive in the lowest rank range (lignite to lower subbituminous).

3. Occurrence

3.1. Coal Seam Occurrence

Although coal particles are scattered throughout many rock units, most coal occurs in seams, which can range in thickness from a few centimeters to over 100 m. In most of the world, anthracite and bituminous coals occur in thinner seams of 1 – 2 m while the lower rank coals, lignite and subbituminous, commonly occur in thicker seams of up to 20 – 30 m, and sometimes more than 100 m (Germany, Australia). While many seams, even minable seams, are of a limited size area, some seams continuously underlie large areas. The Pittsburgh coal seam, for example, extends over 77 700 km^2 in Pennsylvania, Ohio, West Virginia, and Maryland, and it is of minable thickness for over 15 540 km^2.

In some coal basins, there are hundreds of named coal seams, but normally only a few are of the quality, thickness, and size of area to be extensively exploited commercially. Other coal basins exist, where only one to three coal seams are developed in minable tickness.

3.2. Coal Seam Structures

All coal seams have a number of structural features, including partings, splits, rolls, cutouts, cleats, faults, folds, and alterations caused by igneous intrusions. These features strongly affect the mining and economical recovery of the coal. *Partings* are layers of rock, usually shale or sandstone, that occur within a coal seam and were caused by an influx of sediment into the original coal swamp. In commercial seams, the partings must, of necessity, be few and thin (a few centimeters). However, even in such seams the partings can be very extensive. When the thickness of a layer of rock within a seam increases to the point where it is no longer practical to mine the parting with the coal, the seam can be considered to have *split.* Although some seams split into three or more minable seams, the splitting of one seam into multiple seams can present serious problems in mining, including correlation (i.e., tracing a given seam across a zone, e.g., a valley, where it is missing) and loss of minable thickness.

In addition to partings and splits within the coal seam, the upper and lower surfaces of a seam often pinch and swell to change the coal seam thickness. Such features have been called *pinches, rolls, horsebacks*, and *swells*, and their occurrence at the base of a seam is usually attributed to differential compaction. Roof rolls are common and the protrusion of rock into the coal causes some serious problems with mine roof stability. *Cutouts* or stream washouts are the extreme cases where the protrusion actually eliminates the coal seam. These features are clearly the result of nondeposition or erosion by ancient streams associated with the coal swamps.

Another important feature of coal seams, especially in bituminous coals, is the presence of closely spaced fractures within the coal. These fractures, called *cleats*, are usually perpendicular to the bedding plane of the coal and com-

monly occur in two sets perpendicular to each other. This gives the coal a tendency to break into blocks. The cleat controls the ease with which the coal breaks up, and it has long been used in coal mining. The most prominent cleat is called the face cleat because the working face of a mine is often parallel to it. The other cleat is called the butt cleat. Cleats give coal high permeability to gas and groundwater and also act as sites of mineral deposition. Calcite and pyrite are the most common cleat-filling minerals, although other minerals including gypsum can occur.

Faulting and folding of coal seams by geological forces can also be important features. Seams that are faulted or folded usually cannot be mined by surface methods and are more expensive to mine than flat seams. When faulting is extensive, even thick seams of high quality may be too discontinuous to mine. On the other hand, folding can double the minable thickness of some seams.

The *alteration* of coal seams by dikes, sills, and other types of igneous intrusions is widespread and is a serious problem in some coal fields, such as those in the Rocky Mountains of the United States or in the Natal coal fields in South Africa, which have been affected by dolerite intrusions. The alteration is thermal and causes an increase in carbon content and a decrease in hydrogen, moisture, and volatile matter. In the contact zone, the coal may be transformed into natural coke. On the other hand, mining is rendered difficult because of the hard igneous rocks.

3.3. Coal Seam Distribution

Although coal seams are found in rocks of all geologic ages since the Devonian, the age distribution is not even. The first sequences of real coal seams formed from higher terrestrial plants occur in Carbonaceous shales and sandstones of Upper Devonian age. The classical example is the coal deposit of the Bear Island (Norway). Major coal deposits of Carboniferous age occur in eastern and central North America (Pennsylvania, Illinois, Newfoundland, Nova Scotia, Cape Breton Island), in north western Europe (British Isles, Ruhr and Saar-Lorraine coal fields, Upper Silesian coal fields), and the Ukrainian coal fields. Major deposits of Permian age occur in South Africa (Witbank and Natal coal fields), South America (Morungava coal basin) India (e.g., Raniganj and Darjeeling coal fields), Australia (Greta and Tomago coal measures, Collie and Coorabin coal fields), China, and Antarctica. In late Triassic and Jurassic times the major coal accumulation was in Australia (Calide and Milmerran coal, Gunnedah and Eromanga coal basin, Wallon coal field), and parts of the former Soviet Union and China. Coal deposits of the Cretaceous period are found in the Rocky Mountains of North America (Baltimore canyon trough, Cordillera, Foothill belt, Arctic archipelago, Kootenay coal), in New Zealand, and Spitzbergen. The last great period of coal deposition was in the Tertiary period. Coals originating from this time are found in central and south eastern Europe (Germany, Poland, Czechia, former Yugoslavia, Romania, Bulgaria, Greece), Russia, Australia (Victoria, Gippsland basin), New Zealand, Japan, China, Indonesia, United States (Western coal, Texas) and Canada (Arctic Archipelago, British Columbia). Because the coal deposits of Cretaceous and Tertiary age are younger than the Carboniferous and Permian coals, these coals tend to be of lower rank, usually subbituminous or lignitic, in comparison with the older bituminous and anthracitic coals. However, there are many exceptions to the rule.

The distribution of coal seams throughout the world is also not uniform. As shown in Figure 1, more than 90 % of the world's coal resources are located in the northern hemisphere. Although the figures vary from source, China, the former Soviet Union, and the United States together have about 75 % of the total coal resources and reserves. Each of these countries has a coal production of $> 500\times10^6$ to $> 1000\times10^6$ t/a.

Figure 1. Geographic location of the world's coal

Table 3. Classification of coal by rank [a]

Class	Group	Fixed carbon limits, % (dry, mineral-matter-free basis)		Volatile matter limits, % (dry, mineral-matter-free basis)		Calorific value limits, Btu/lb (moist, mineral-matter-free basis) [b]		Agglomerating character
Anthracite	metaanthracite	≧98	–	–	≦2	–	–	nonagglomerating
	anthracite	≧92	< 98	> 2	≦8	–	–	nonagglomerating
	semianthracite [c]	≧86	< 92	> 8	≦14	–	–	nonagglomerating
Bituminous	low-volatile bituminous coal	≧78	< 86	> 14	≦22	–	–	commonly agglomerating [e]
	medium-volatile bituminous coal	≧69	< 78	> 22	≦31	–	–	commonly agglomerating [e]
	high-volatile A bituminous coal	–	< 69	> 31	–	≧14 000 [d]	–	commonly agglomerating [e]
	high-volatile B bituminous coal	–	–	–	–	≧13 000 [d]	< 14 000 [d]	commonly agglomerating [e]
	high-volatile C bituminous coal	–	–	–	–	≧11 500	< 13 000 [d]	
						≧10 500	< 11 500	agglomerating
Subbituminous	subbituminous A coal	–	–	–	–	≧10 500	< 11 500	nonagglomerating
	subbituminous B coal	–	–	–	–	≧ 9 500	< 10 500	nonagglomerating
	subbituminous C coal	–	–	–	–	≧ 8 300	< 9 500	nonagglomerating
Lignitic	lignite A	–	–	–	–	≧ 6 300	< 8 300	nonagglomerating
	lignite B	–	–	–	–	–	< 6 300	nonagglomerating

[a] This classification does not include a few coals, principally nonbanded varieties, which have unusual physical and chemical properties and which come within the limits of fixed carbon or caloric value of the high-volatile bituminous and subbituminous ranks. All of these coals either contain < 48 % dry, mineral-matter-free fixed carbon or have > 15 500 Btu/lb moist, mineral-matter-free.
[b] Moist refers to coal containing its natural inherent moisture but not including visible water on the surface of the coal.
[c] If agglomerating, classify in low-volatile group of the bituminous class.
[d] Coals having 69 % or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of caloric value.
[e] It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class, and there are notable exceptions in high-volatile C bituminous group.

4. Classification

Coal is combustible and should be composed of more than 50 wt % carbonaceous material [8, 9]. Commercially, coal is classified in a number of ways on the basis of (1) the original plant or maceral composition, sometimes called coal type, (2) the degree of maturity or metamorphism, called coal rank, (3) the amount of impurities such as ash or sulfur, called coal grade, and (4) the industrial properties such as coking or agglomeration.

The various bands or layers in coal evident to the unaided eye have also been classified into four types [10]. *Vitrain* layers appear bright and vitreous; *clarain* appears as relatively less bright, striated layers; *durain* is dull and featureless; *fusain* layers are dull gray and like charcoal. Although these terms (all ending in ain) are megascopic terms meant to be applied to hand-specimen samples, they do have some compositional implications at the microscopic level. For example, vitrain layers contain mainly vitrinite macerals, fusain layers contain mainly inertinite macerals, and clarain and durain are mixtures of all three maceral types.

The most important classification for commercial purposes in the United States and many other countries is the ASTM classification by rank. It is the basis on which most of the coal in the United States is bought and sold. This classification, ASTM Standard D 388 shown in Table 3, divides coals into 4 classes, anthracite, bituminous, subbituminous, and lignitic, which are further subdivided into 13 groups on the basis of fixed carbon and volatile matter content, calorific value, and agglomerating character. The fixed carbon and volatile matter values

are on a dry, mineral-matter-free basis and the calorific values are on a moist, mineral-matter-free basis. In this system, coals with $\geq 69\,\%$ fixed carbon are classified by fixed carbon content and those with $< 69\,\%$ fixed carbon content are classified by calorific value. Thus, all lignitic and subbituminous coals and the lower rank bituminous coals are classified by their calorific value. It is also important to note that not all coals can be fitted into this system. This is especially true of coals with a high liptinitic maceral content, such as cannel and boghead types.

In the last two decades coal classification has been discussed extensively. These discussions involve exchange of ideas, e.g., with the Economic Commission for Europe of the United Nations (ECE-UN). As a result the "International Codification System for Medium and High Rank Coals" (exclusively for commercial and utilization purposes, involving the international coal trade) has been formalized and approved. With this new codification system (ECE-Coal-115, 1988) producers, sellers, and purchasers can communicate unambiguously about the quality coal must possess to be suitable for certain industrial applications (e.g., combustion, carbonization, gasification, or hydrogenation) as well as general and environmental aspects of coal quality. This system is applicable to all bituminous coals of different origin and geological age. It is also relevant for all seam coals, multiseam blends of run-of-mine coals, raw, and washed coals. The threshold between low-rank and higher-rank (medium- and high-rank) coals is defined and set at a gross calorific value (moist, ash-free basis, i. e., maf) of ≥ 24 MJ/kg, provided the mean random reflectance of the vitrinite is $\geq 0.6\,\%$.

The coals are characterized by eight coal property-related parameters which use a 14-digit code number to describe the rank of the composition of the coal types and the quality of the coal (see Table 4). These include the mean random reflectance (Rr %), reflectogram (distribution of reflectance readings), maceral group composition index, swelling crucible number, volatile matter content (dry, ash-free basis, i..e., daf) ash content (dry basis, db, in %), and gross calorific value (daf, MJ/kg).

A summary of the codes for medium- and high-rank coals is given in Tables 5 and 6. Table 7 presents an example of coal coding, a carboniferous coal blend from the northern hemisphere with good coking properties.

Table 4. International codification system for medium- and high-rank coals

Basic parameters	Digit
(a) Mean random reflectance of vitrinite Rr, %	1; 2
(b) Characteristics of the reflectrogram (standard deviation, gap(s))	3
(c) Maceral group composition index, % by volume (mmf) [a] digit 4 = Inertinite, digit 5 = Liptinite	4; 5
(d) Crucible swelling number	6
(e) Volatile matter content, mass % (daf) [b]	7; 8
(f) Ash content, mass % (db) [c]	9; 10
(g) Total sulfur content, mass % (db)	11; 12
(h) Gross calorific value, MJ/kg (daf)	13; 14

[a] mmf = mineral-matter-free;
[b] daf = dry, ash-free;
[c] db = dry basis

A codification system for low-rank coals, i.e., coals with a gross calorific value (maf) of < 24 MJ/kg and a mean random reflectance of the vitrinite (Rr) $< 0.6\,\%$ has not been drawn up until now and will be dealt with by the ECE-UN at a later stage. Additional parameter for subdivision of these low-rank coals may be total moisture content (as-received basis, mass %), ash content (db, mass %), and total sulfur content (db, mass %).

An "International Classification of In-seam Coals" for geological assessment of coal deposits, coal mining, and industrial purposes has been developed by the ECE-UN Working Party on Coal (Fig. 2). The work was supported by the ICCP, the International Energy Agency (IEA/OECD) and the ISO. The classification is not to be used for commercial or trade purposes. The systematization of coal is based on three fundamental characteristics which, according to the present knowledge, provide clear discrimination (a schematic version is given in Figure 3). The characteristics are (1) rank (degree of coalification; (2) type (petrographic composition); and (3) grade (amount of impurities). The main rank divisions lignite, subbituminous, bituminous, or, alternatively, low-, medium-, and high-rank coals are based on the vitrinite mean random reflectance (Rr, %) and gross calorific value (GCV, MJ/kg). Petrographic composition is expressed in terms of maceral group analysis, i. e., the vitrinite (V), liptinite (L), and inertinite (I) content in vol %, all mineral matter free (mmf).

Table 5. International codification system (digits 1 – 6) for medium- and high-rank coals

	Random reflectance of vitrinite, %		Characteristics of reflectogram			Maceral group composition index, vol % (mmf) [a] 4 = Inertinite; 5 = Liptinite				Swelling crucible number	
Digit	1 ; 2		3			4		5		6	
Code no.	02	0.20 – 0.29	0	≤ 0.1;	no gap	0	0 – < 10	0	exempted	0	0 – 1/2
	03	0.30 – 0.39	1	> 0.1;	≤ 0.2; no gap	1	10 – < 20	1	0 – < 5	1	1 – 11/2
	04	0.40 – 0.49	2	> 0.2	no gap	2	20 – < 30	2	5 – < 10	2	2 – 21/2

	06	0.60 – 0.69	4		2 gaps	4	40 – < 50	4	15 – < 20	4	4 – 41/2
	07	0.70 – 0.79	5	more than 2 gaps		5	50 – < 60	5	20 – < 25	5	5 – 51/2
	08	0.80 – 0.89				6	60 – < 70	6	25 – < 30	6	6 – 61/2
	09	0.90 – 0.99				7	70 – < 80	7	30 – < 35	7	7 – 71/2
	10	1.00 – 1.09				8	80 – < 90	8	35 – < 40	8	8 – 81/2
	11	1.10 – 1.19				9	≥ 90	9	≥ 40	9	9 – 91/2
	12	1.20 – 1.29									
	13	1.30 – 1.39									
	14	1.40 – 1.49									
	15	1.50 – 1.59									
	16	1.60 – 1.69									
	17	1.70 – 1.79									
	18	1.80 – 1.89									
	19	1.90 – 1.99									
	20	2.00 – 2.09									
	21	2.10 – 2.19									
	22	2.20 – 2.29									
	23	2.30 – 2.39									
	24	2.40 – 2.49									
	25	2.50 – 2.59									
	26	2.60 – 2.69									
	27	2.70 – 2.79									
	28	2.80 – 2.89									
	29	2.90 – 2.99									
	30	3.00 – 3.09									

[a] mmf = mineral-matter-free

A differentiation between banded (mainly humic) and nonbanded coals (sapropleic coals) has also been made. The boundary limits for the grades are defined by ash content (db) in mass %.

Figure 2. Schematic version of the International Classification of In-seam coal (1995)

5. Chemical Structure of Coal

The *organic components* of coal consist of a complex mixture of macromolecular carbon compounds of varied chemical constitution. The heterogeneity of coal is well-known from optical studies of thin coal sections. The microscopically distinct and distinguishable maceral groups of vitrinite, liptinite, and inertinite, their proportions, and the association of macerals of several groups with each other are essentially responsible for the physical, chemical, and technological properties of a particular coal. Preformed macerals derived from transformation of the original lipidic, woody, and waxy plant matter under varying oxidizing and reducing conditions and processes are present in *peat* and *soft lignites.* Temperature-induced chemical changes of these macerals and increased pressures influencing the physical structure of the material undergoing coalification have led to the formation

The *minerals* of coal play a considerable part in the industrial use of coals of all ranks. The mineral content, its distribution within the coal, and its composition may affect carbonization, gasification, combustion, and liquefaction processes by modifying the process of coal depolymerization and influencing hydrogenation and the thermal behavior of the resulting ash under both oxidizing and reducing conditions.

Besides microscopically unidentifiable plant ash, coals contain varying amounts of *syngenetic* and *epigenetic* minerals, which entered the organic coal substance during the first or second phase of coalification, respectively. They have either grown together with the organic substance or are physically separable. Generally, medium to high ash coals contain epigenetic minerals. Structure and hardness bear considerable influence on the distribution in the various fractions of the crushed coal from coal preparation plants. The mineral structure of coal ash is extremely difficult to determine. Low-temperature combustion in oxygen plasma produces an ash that can be analyzed by X-ray diffraction and IR absorption spectrometry. Deductions must also be made from the chemical analysis of the oxides present in the ash. The major constituents of coal ash as determined by this chemical analysis are

SiO_2, Al_2O_3, Fe_2O_3, and CaO, in addition to MgO, Na_2O, K_2O, BaO, TiO_2, P_2O_5, and SO_3.

These oxides may be derived from minerals of the following types originally present in the coal: kaolinite, illite, and bentonite as major clay minerals; calcite or siderite as major carbonates; pyrite or marcasite as the sulfides; and many other minor minerals such as apatite, hematite, rutile, quartz, etc.

5.1. Characterization of Coals

5.1.1. Standard Analytical Methods

Coals are characterized by various chemical and physical methods that have been established as national and international standards. These include proximate analysis, carbonization assay, ultimate analysis, heating value (calorific value) determination, sulfur distribution, caking and coking behavior, ash composition, and fusibility.

The above tests are carried out on representative prepared coals, using either as-received (by the laboratory) or predried samples. The results are commonly expressed on an as-received, dry (d), dry ash-free (daf), or dry mineral-matter-free (dmmf) basis.

Figure 3 shows the comparison and relationship between the proximate and ultimate analyses as well as the carbonization assay.

Figure 3. Comparison of proximate and ultimate analysis with carbonization assay C, H, O, N, S = elements; T = tar; W* = decomposition water; G* = carbonization gas; VM = volatile matter

In Figure 4 the sulfur forms occurring in coals are illustrated. Figure 5 shows selected typical distributions of mineral components.

The coalification series, expressed by plotting atomic ratios of H/C vs. O/C, is graphically represented in Figure 6. As one moves from right to left, i.e., from peat to bituminous coals, the diagram shows only a slight shift to somewhat lower H/C ratios while the O/C ratios steadily decrease. At an O/C level of ca. 0.05, a steep decline in the H/C ratio occurs when the anthracitic coals are reached. Examples of actual compositions of various coals of different degrees of coalification are given in Table 8.

Figure 6. Coalification series: atomic ratios H/C vs. O/C

5.1.2. Laboratory and Bench-Scale Simulation Tests

Because of the complex structure of coal and its vastly varying composition, its depolymerization, liquefaction, and combustion characteristics in thermal and extractive applications are somewhat unpredictable. In commercially operated processes, they depend very much on the prevailing conditions, such as heating and flow rates, pressure, and gas or solvent composition.

Therefore, it is often necessary to evaluate coal properties further by subjecting samples to thermal, extractive, and mechanical tests, assessing on a small scale the expected behavior and at the same time providing for study of the types and compositions of specific reaction products.

Such experiments that yield fragmental decomposition compounds can also be employed for the structural identification of coals.

The determinations include, e.g., pyrolytic or progressive devolatilization tests, extraction or solubility studies, performance of selected coking tests, reactivity measurements on specially prepared cokes, grain stability evaluation, and ash slagging behavior.

5.1.3. Petrographic Studies

The determination of the petrographic composition of coals by maceral group analysis is a valuable tool for assessing structural aspects and predicting coal behavior. Usually it also incorporates the determination of the degree of coalification by measuring the reflectance of the vitrinite as the most important and abundant group of macerals. This method allows a ranking or classification of coals by their degree of coalification and, hence, identifies the type of coal. It also reveals specific phenomena that may have induced structural coal changes within the geochemical stage of coal formation, such as aging or contact coalification due to inflowing magma.

5.2. Structural Deductions from Analytical and Bench-Scale Data

The results of coal analyses predict thermal decomposition products (proximate analysis, carbonization assay, caking and coking tests) and the element composition (ultimate analysis). Furthermore, the moisture level of run-of-mine coals is indicative of the capillary structure, allowing a first tentative classification of a particular coal. The lack of moisture holding capacity of highly coalified coals is proof of an increasingly densified structure. The element ratio, particularly that of H/C and its change to lower values as coalification progresses, points toward the aromatization of structural groups. Likewise, the dramatic decrease in oxygen within the series

peat to anthracite strongly suggests the loss of functional end groups.

The softening properties of bituminous coals (caking and coking tests) reveal the mobility of fragmented decomposition products, observed particularly in coals with high hydrogen and, hence, high vitrinite and liptinite contents. On the other hand, oxygen-rich coals, i.e., low-rank coals with an associated appreciable inertinite content or highly aromatic coals with a high degree of cross-linkage, yield recondensed solid depolymerization products. The tar and gas composition (carbonization assay, devolatilization, caking, and coking tests) shows that hydrogen preferentially enters liquid and gaseous components due to rearrangement [13].

Stable fragments, obtained from specific pyrolysis or hydropyrolysis studies, indicate the major types and the volatility of aromatic molecules present in a particular coal. Liquid-phase treatment produces larger unit fragments, which can be determined analytically. A petrographic survey permits selective composition analyses and structural identification of individual major maceral groups such as vitrinite.

5.3. Bonding of Elements in Coal

Thermal depolymerization by controlled slow or flash pyrolysis of coals, oxidation, hydrogenation, liquefaction of coals, supercritical and selective solvent extraction, as well as the application of modern physical techniques such as X-ray diffraction, IR spectroscopy, nuclear magnetic resonance, or pyrolysis mass spectrometry have furnished extensive data on the bonding of elements in coals. Major findings from these investigations are [14]:

Carbon: The aromaticity increases from 40–50 % C in subbituminous coals to 70–80 % C in bituminous coals and is over 90 % C in anthracites.

Hydrogen: Aromatic bonding to carbon and as aliphatic hydrogen in, e.g., methylene ($-CH_2-$) and methyl ($-CH_3$) groups occurs.

Oxygen: Major functional groups are hydroxyl ($-OH$), carboxyl ($-COOH$), carbonyl ($=C=O$), etheric ($-O-$) and heterocyclic oxygen.

Sulfur: Bonding is predominantly as thiophenes, also in the thiolic form ($R-SH$), decreasing with higher rank coals; up to ca. 25 % S is present as aliphatic sulfides ($R-S-R$). Heterocyclic sulfur compounds are also known to exist.

Nitrogen: Very little information on organic nitrogen bonding is available. It appears to occur in heterocycles.

5.4. Structural Evidence of Coals

Much data on the structural aspects of coal has been accumulated and published [15, 16]. The overall picture, however, is still very incomplete. The difficulty is that coal is a highly heterogeneous mixture and, as such, is not a clearly defined macromolecular aromatic compound of uniform molecular mass and structure. Thus, evaluated structural parameters refer to isolated fragments, components (vitrinite), or constituents. Nevertheless, coal may be described structurally as a three-dimensional skeleton of generally four to five highly stable condensed aromatic and hydroaromatic units with cross-linkage by weaker short-chain aliphatic groups. Reactive functional end groups and aliphatic structures are attached to the aromatic skeleton. The average molecular mass distribution is ca. 500–800 for low-rank coals, increasing to ca. 3000–6000 for bituminous coals, and possibly values in excess of 100 000 for anthracites.

Various overall models for the complex organic structure of coals, combining available experimental data on structural fragment analysis, have been tentatively proposed. However, none as yet fully accounts for all the phenomenological characteristics [14].

6. Coal Mining

6.1. General Considerations

A coal deposit is the final result of the cumulative effects of decaying vegetation, deposition of sediments, movements of the earth crust, and forces of erosion. The transformation of the vegetation in swamps into peat, lignite, anthracite, and bituminous deposits is associated with high pressure or high temperature. Movements of the earth crust (folding and faulting), igneous intrusions, and wind and water erosion have played

important roles in determining the inclination, continuity, and quality of the seams (see Section 3.2). These have also resulted in (1) changing the position of the coal seams relative to the surface of the earth, (2) altering the condition of the roof and floor of the coal seams, (3) eroding away of entire seams or portions of seams, (4) outcropping of the surface of otherwise concealed seams, and (5) determining the economic and technical feasibility of mining these coal seams [17, 18].

The various methods of mining a coal seam can be classified as surface or underground, depending on whether the coal seam is exposed and recovered from operations on the surface of the earth or from operations in underground openings, approached from suitably located surface openings. The results of an analysis of the world coal production by mining method and rank of coal are summarized in Table 9. Bituminous and lignite seams account for over 65 and 25 % of the world production, respectively. Ten countries account for nearly 75 % of the total production. Contributions from surface and underground mining to worldwide production are approximately equal; however, by country the production distributions are quite variable. In general, most anthracite production is from underground mines, and almost all lignite production is from surface mines.

Decisions on whether a coal seam will be mined and the mining method to be practiced on a given coal seam depend on many technological, economic, and social factors. Very often, the technological factors, the most important of which are associated with geology, constrain the mining engineer to a single mining method. However, at any given time, economic and social factors dictate whether a coal seam can be mined at all.

6.2. Surface or Underground Mining

The key to determining whether to mine a coal seam by a surface or underground method is the *stripping ratio.* Distinction is often made between several stripping ratio calculations. The first is the calculation of the stripping ratio of the areas over the coal seam. It is generally defined as the number of cubic meters of the strata overlying the coal seam for every ton of coal in the seam. The basic inputs are the thicknesses of the coal seam and the strata overlying the coal seam.

$$\text{stripping ratio} = \frac{\text{cubic meters of strata material over a specified area of coal seam}}{\text{tons of coal in the same specified area of coal seam}} \quad (1)$$

The second is the calculation of a stripping ratio at which recovery by surface mining is equivalent in cost to recovery by the underground method. The basic inputs are the costs of mining that reflect the mining technology to be used.

$$\text{break-even stripping ratio} = \frac{\left\{\begin{matrix}\text{underground}\\ \text{mining cost}\\ \text{per ton of coal}\end{matrix}\right\} - \left\{\begin{matrix}\text{surface mining and}\\ \text{reclamation cost}\\ \text{per ton of coal}\end{matrix}\right\}}{\text{surface mining cost per cubic meters of strata above the coal seam}} \quad (2)$$

Only those parts of the coal seam for which the stripping ratio calculated by Equation (1) does not exceed the stripping ratio shown in Equation (2) should be mined by surface mining methods.

A third stripping ratio, also called break-even stripping ratio, incorporates the technology of mining and the market value of coal produced. It is calculated as follows:

$$\text{break-even stripping ratio} = \frac{\left\{\begin{matrix}\text{sales realiza-}\\ \text{tion per ton}\\ \text{of coal}\end{matrix}\right\} - \left\{\begin{matrix}\text{total cost of produc-}\\ \text{ing and marketing}\\ \text{per ton of coal}\end{matrix}\right\}}{\text{surface mining cost per cubic meters of strata above the coal seam}} \quad (3)$$

6.3. Coal Methods

The mining methods in coal surface mines are dictated by geological and topographical conditions, i. e., the thickness and inclination of the coal seams, the thickness of the overlying strata, and the topographical relief. The hardness – or better: cutting resistance – of the overburden and coal is of special importance for the selection of the excavation method. Hard rock formations having an uniaxial compressive strength of about more than 20 MPa must be loosened before digging, whereas soft material (loose rock and soil) can be excavated directly. The loosening of the hard rock is as a rule effected by blasting, in special cases, e.g., when blasting is not possible for environmental reasons, by ripping.

Figure 7. Rope controlled shovel excavator working in the Gilette coal mining district (Wyoming/USA)

Figure 8. Dragline working in a typical coal strip mine

Typical mining machines in hard rock mines are shovel excavators and wheel loaders. Shovel excavators are either rope controlled (Fig. 7) or operate with a hydraulic system. Shovels and wheel loaders are *discontinuously working mining machines* equipped with one bucket. Also draglines (Fig. 8) belong to this group of machines.

Soft material is usually mined by bucket wheel excavators (Fig. 9) or bucket chain excavators (Figs. 10 and 11), which belong to the *continuous mining systems* because here the bucket wheel or the bucket chain create a continuous flow of material.

Also bulldozers and scrapers find extensive application in surface mines, e.g., in scalping the surface, removing the topsoil and preparing the mining area for subsequent operations.

Figure 9. Bucket wheel excavator with a daily capacity of 240 000 m^3 working in the Renish lignite district in Germany, the machine weighs 13 000 t (Courtesy: Rheinbraun, Cologne)

Overburden removal is the most important unit operation in many mines. The equipment used varies from wheel loaders to shovel excavators, draglines, bucket wheel excavators, and bucket chain excavators. In multi-seam coal mines, where inert partings have to be removed between the split seams, usually on the same bench overburden and coal have to be excavated by the same machine. Two basic methods exist to transport the waste material to the inside dump: Cross-pit hauling and around-the-pit hauling.

Cross-Pit Hauling. Because of the short hauling distance the cross-pit method is the most economic one, but it cannot be applied everywhere. The following cross-pit equipment systems are in use:

- Draglines or shovels for direct casting (Strip mining systems)
- Bucket wheel excavators with long discharging boom
- Direct connection of excavator and spreader
- Conveying bridges

Bucket wheel excavators with a long discharging boom are applied in several mines. In Texas two systems of this type are in operation. Figure 12 shows a model of the type of machines working in the "Big Brown" lignite mines. The discharging boom has a length of 205 m and crosses an underlying dragline system and the exposed coal seam. Typical strip mining systems are usually equipped with draglines (Fig. 13) [19]. In the German lignite district south-east of Berlin giant conveyor bridges are in operation. They are equipped with three big bucket chain excavators and can remove 100×10^6 m^3 of overburden per year (Fig. 11).

Figure 10. Cross-section of an Australian lignite mine equipped with bucket wheel excavators (BWE) and a bucket chain excavator (BCE) on the lowest bench [19]

Figure 11. Cross-section of a conveying bridge of the F 60 type, equipped with three bucket chain excavators. The unit has a daily capacity of up to 500 000 m^3 and weighs 26 000 t. Several machines of this type are installed in the LAUBAG lignite mines south-east of Berlin/Germany

Around-the-Pit Hauling. For the around-the-pit-hauling process either off-road trucks or belt conveyors are used. Railway systems, which were applied in surface mining earlier, have meanwhile been replaced nearly everywhere. Particularly in hard rock mines the blasted material is transported by *trucks* with a loading capacity of up to 300 t. For heavy trucks two driving systems are available. The mechanical system, derived from road trucks and equipped with a special multi-disk, oil-cooled brake system, and the diesel-electric system. Here the drive assembly consists of a diesel engine, a generator and an electrical wheel motor in the rear axle. These trucks have an electrical brake system.

Continuously operating *belt conveying systems* are used in many branches of industry involving bulk handling. Prerequisites for their application on the operating benches of surface mines were – besides a high performance – an easy switch of material flow and shiftability without dismantling, because the conveyors must follow the mining advance.

In many coal mines, where the seam is split, coal and overburden have to be excavated from the same bench. Therefore a flexible conveying connection is required. The common solution for this problem is a conveyor distribution yard at the flank of the mine (Fig. 14). Here, by means of telescopic drive heads the material flow can be switched, e.g., from the coal bunker to the waste dump and vice versa.

The second aspect is the track shifting of the bench conveyors. The belt has to follow the operating advance without dismantling. This operation is carried out by heavy bulldozers equipped with a side-crane. After release of the belt ten-

Figure 14. Conveyor distribution yard in a Renish lignite mine in Germany. The shiftable conveyors on the different benches (in the background) feed via link conveyors onto conveyors with telescopic driveheads. Their feeding points can be put on the required conveyor, depending on the material (Courtesy: Rheinbraun, Cologne)

sion the conveyor becomes flexible and can be pulled sideways using a rail with a fixed roller set located at the crane head. For loading the blasted material belt conveyors are applied – instead of or besides trucks – also in hard rock mines, where shovel excavators or wheel loaders are used. But contrary to trucks, belt conveyors cannot take the blasted rock as it is. Before it can be loaded onto the conveyor, it has to be crushed to a grain size of about 300 mm. The crushers are either directly connected with the mining machine or they are – as semi-mobile crushers – located at a central point of the mine. In this case trucks are used for the first section of hauling distance. This hauling concept is advantageous in deep open-pit mines with a high lift, because belt conveyors have, contrary to trucks, no lifting deadweight.

In multi-seam coal mines selective operation is necessary in order to separate coal from inert intercalations. Suitable machines for selective operation are bucket wheel excavators or backhoe shovels. But if a very accurate cut at the interface of the different layers is required, also continuous surface miners are used. This type of machines is derived from surface cutting machines applied for road repair works and operates successfully in several coal and limestone mines all over the world. Because of their high cutting force ground preparation by blasting can be dispensed with.

Reclamation (→ Soil). The reclamation of land used for surface mining operations has become extremely important and is usually carried out very carefully. In the large German lignite mines where the overburden dumps are operated with conveyor belts and spreaders (Fig. 15) these machines cover the dump surface with fertile soil (loess). For *agricultural reclamation* the surface is leveled, a road network combined with a sur-

face drainage system is constructed, and subsequently, for five to seven years, farmers employed by the mine operator cultivate the farmland until the full crop is achieved and the land can be given back to farmers. For *forest reclamation* either loess or – particularly in slope areas for stability reasons – a mixture of loess and quaternary gravel is used as topsoil.

Figure 15. Spreader in a Rheinish lignite mine. The top material, which is laid-on by the machine, consists of fertile soil (loess) for land reclamation [21]

6.4. Underground Coal Mining Methods

Underground coal mining is a complex operation where the working environment of the miners and equipment is completely enclosed by the geological medium overlying and underlying the coal seam. Therefore, the correct assessment of the geological factors is more critical for an underground mine than for a surface mine. The depth to the coal seam, its thickness and quality, the conditions of roof and floor strata, and the problems associated with methane and water inflows must be analyzed in detail to select the appropriate applicable methods and equipment.

An underground mine can be classified as a shaft mine, a drift mine, or a slope mine, depending on the type of access from the surface to the coal seam, as shown in Figure 16. Where applicable, drift is the obvious choice for access to a coal seam. In other cases, the choice between slope and shaft for deep mines can be difficult. A mine with large daily production and a long life would benefit from a slope opening for hauling coal.

Figure 16. Types of access to a coal seam
Deep coal seams can be accessed only by sinking vertical shafts

Two distinct activities in underground coal mining are the unit operations in the production and hauling of coal and the auxiliary operations that are essential to maintaining a safe productive operation. Specifically, the unit operations include cutting, drilling, blasting, loading, and hauling. Auxiliary operations include ventilation, drainage, power, communications, and lighting. Roof support operations in the face area (active face where coal is being mined) can be considered as a unit operation. Support of other areas in the mine can be included in the auxiliary operations. The roof support used in most coal mines is a 1.5 – 2 m long, 15 – 25 mm diameter

steel bolt, usually set in rows such that the bolts are 1.2 – 1.8 m apart in a row, with the rows 1.2 – 1.8 m apart. Additional supports may be used as required.

There are several theories which explain how rock bolts hold the roof. These include the beam theory (roof bolts tie together several weak roof strata into one strong beam), the suspension theory (the weak members are suspended from a strong anchor horizon), and the keying effect theory (the roof bolts act much like the keystone in an arch).

There are two major systems of underground coal mining: the room and pillar and the longwall. There are many variations in each of the systems. Several types of equipment – cutting machines, drills, loaders, roof bolters, shuttle cars, belts, etc. – are used in the mining process, depending on the method chosen to extract a coal seam; the choice is determined by local geological conditions and operating practices.

Two main types of room and pillar systems are the conventional and continuous mining systems, shown in Figure 17. In the former, the operations of cutting, drilling, blasting, and loading are performed by separate machine units. In the latter, a continuous miner rips the coal from a coal seam and loads it directly into a hauling unit, all in one step. In either system, the objective is to create blocks of coal, usually rectangular or square, during the first stage of the mine,

Figure 17. Conventional and continuous room and pillar underground mining systems

Figure 18. Development plan for a conventional room and pillar mining section (lengths in feet; 1′ = 0.305 m)

Figure 19. The milling-head continuous miner
The coal is cut by the picks mounted on a number of oscillating and rotating disks. The cut coal is loaded onto a chain conveyor in the machine by a gathering arm in the loading head

Figure 20. Development plan for a five-entry continuous room and pillar mining section (lengths in feet; 1′ = 0.305 m)

called "development." These blocks of coal may be left in place. However, they may also be recovered during the second stage of mining, usually called "pillaring." Where the surface features (such as houses, roads, streams, etc.) have to be protected, pillars underneath these features are not recovered. In the United States, the average recovery from a coal seam, when room and pillar methods are used, is ca. 50 %. The sequence of operations for the various machines in a conventional mining development plan is shown in Figure 18. After finishing its operation in a working area (or face), a machine moves to the next higher numbered working area. Because of the large number of machines, there is a need to have a large number of working faces to avoid excessive delays.

Continuous mining incorporates the unit operations of cutting, drilling, blasting, and loading into one machine: the continuous miner. There is no need for a large number of working faces. While there are many types of continuous miners, the milling-head miner, shown in Figure 19, is by far the most popular machine in operation. The sequence of operations for the continuous miner in a five-entry development is shown in Figure 20. The only other machine unit that cycles with the miner is the roof bolter. The ventilation plan has been laid out such that the miner and the roof bolter operations can have their own split of ventilating air current. To a large extent, continuous mining has replaced conventional mining. However, in thick and hard coal seams, conventional mining has great potential for increased production.

Figure 21. Open-end method of pillar extraction [22]
The pillar extraction must be sequenced to maintain the 45° lineThe methods that are practiced to extract the coal left in the pillars depend greatly on the na-

ture of roof and floor and the manner in which the increased pressure generated due to pillaring is transferred to other pillars and the gob. The necessary evaluations are specific to each site and must ensure that sudden bumps and coal eruptions do not result. In addition, the unrecovered pillars should not be crushed to a point where loss of life, equipment, or coal is possible. Two methods are shown in Figures 21 and 22.

Figure 23. Perspective and close-up view of longwall system showing the equipment and its arrangement
Note that this is a retreating longwall system

In longwall mining systems, a block of coal 200 – 300 m wide and 2000 – 3000 m long is extracted by a machine that runs up and down the width of the face and takes a 0.75 – 1 m slice of the block as shown in Figure 23. A modern mechanized longwall system is a true continuous coal production system. It offers great productivity and safety. The system is most common in Europe; however, it is gaining popularity in the United States and elsewhere. There are essentially four machines: the cutting machine (usually a shearer or a plough), the armored face conveyor, the line of roof supports, and the stage loader. The cutting machine rides on the conveyor, cutting and transferring coal to it (Figs. 24 and 25). Both of these machines and all of the men in the face are under a protective canopy of steel, formed by a continuous line of roof supports. In modern longwall systems, shields are most common for supporting the roof over the immediate face area.

Figure 24. Plough longwall face in a German coal mine

Figure 25. Shearer longwall face in an American coal mine

There are three main types of longwall system layout. The retreating longwall, shown in Figure 26, is most common in the United States. The advancing longwall, shown in Figure 27, is most common in Europe. The third method, alternate retreat and advance, is not in common practice.

A method combining the longwall layout with continuous miners is known as the shortwall method and is shown in Figure 28. It is also not in common practice, but where conditions are favorable, this method may have great potential.

Mention has already been made about thick and inclined coal seams. Thick coal seams are a special gift of nature. However, thick and steeply pitching seams present challenges to the ingenuity of miners to devise safe and efficient methods for their extraction. A generalized classification of thick-seam mining methods is shown in Table 10.

The cutting action of a water jet has a long history (at least 40 years) of successful application in the Former States of theSoviet Union and other European countries for the extraction of coal. Some important requirements for the application of such hydraulic mining underground are that the coal should be soft or have friable bands to aid in the breaking and that the roof should be competent and part easily from the coal. This allows the maximum extraction of coal before the roof collapses and also minimizes dilution. The floor must resist degradation by water. Where the coal is hard, blasting can aid subsequent water jetting. Under proper conditions, hydraulic mining is very efficient, safe, and productive.

Figure 28. Shortwall mining method
Shortwall is generally 40 – 60 m wide. The cut width is usually 3 m. The roof support equipment (chocks) must be specially designed for the longer cantilever support and is more costly. a) Panel belt conveyor; b) Flexible conveyor train; c) Chock; d) Continuous miner

7. Coal Preparation

The various coal conversion processes require the use of different coal types and qualities. Coal preparation can particularly affect water, ash and sulfur contents, and grain size. Preparation is intended to turn the raw coal into more manageable products with defined properties. Coal preparation includes homogenization, breaking, crushing and screening; cleaning (reduction of sulfur and ash contents); dewatering; and blending. The choice of preparation processes and the

degree of preparation depend (1) on raw coal properties and the demands of the technological processes that follow, (2) the quality requirements on the end products, and (3) on economic and environmental considerations. Coal value but also its selling price increase with the degree of preparation.

About 80 % of hard coal and nearly all of the brown coal presently consumed are used for heat and power generation. Pulverized-coal furnaces are almost exclusively used in large power stations. In this case, the coal is usually mill dried to a water content of 1 – 2 wt % for hard coal and of 15 – 20 wt % for brown coal directly before entering the boilers.

7.1. Hard Coal Preparation

Hard coal preparation is part of the colliery operation. The ROM (run of mine) coal brought to the surface contains various types of accompanying minerals and interstratifications, which must be removed to obtain a coal that complies with market demands for the different types and grades. Grain size, ash content, and moisture content can be controlled within a narrow range by applying mechanical and physical cleaning methods. In general, run-of-mine (ROM) coal is only prepared by size reduction and/or screening. Depending on the use, grain size will vary from micrometer to centimeter size. Pulverized coal can be slurried with water for transportation in pipelines (Chap. 10) [23 – 25]. With water or oil it is slurried in order to replace fuel oil in power stations and industrial boilers and for some gasification processes (e.g., Texaco process, Section 9.4; → Gas Production).

Figure 29. Change in the characteristics of ROM coal
a) Moisture content in particles < 6 mm; b) Fraction of particles < 0.5 mm; c) Refuse content of the ROM coal; d) Fraction of particles < 10 mm

Only about one-third of the hard coal undergoes preparation including cleaning and dewatering. Particularly coal intended for coking process requires extensive preparation in view of the high quality demands on metallurgical coke. Since ash and water are roughage, their contents are reduced for economic reasons. Sulfur has to be removed because it negatively influences the utilization of coke in metallurgical processes. Simultaneously, the emission of sulfur dioxide can be reduced in the primary stages, if coal/coke is used as fuel.

Figure 30. Basic flow sheet of a modern coal preparation plant

Figure 29 shows that the characteristics of raw coals have increasingly deteriorated due to the mechanization of coal retrieval and to the measures adopted to suppress dust. Large mining complexes concentrating on few face areas produce coal with characteristics that fluctuate within a wide range. A raw coal homogenization step can minimize investment and operational costs for new or extended washery buildings needed to handle such diverse coals. It can also improve the precision of separation and, thus, the yield of saleable product and provide a more consistent product.

The sequence of hard coal cleaning procedures is depicted in the flow sheet of a modern washery shown in Figure 30.

7.1.1. Preliminary Treatment

The upper grain size of raw coal is defined by the dimensions of the coal cleaning equipment. Before being fed to that equipment, the coal is subjected to preliminary screening and crushing to a diameter of 120 – 150 mm; foreign matter is simultaneously removed. Coarse dirt is normally reduced in particle size along with the coal, and only in exceptional cases is it removed by preliminary treatment. Such preliminary removal of coarse dirt is done exclusively in drum or inclined separators. Dual eccentric and resonance screens are used for lump coal; each of these machines has a throughput of up to 2×10^3 t/h.

After preliminary screening and removal of foreign matter, the coal in the 0 – 150 (or 0 – 120) mm diameter range is defined as raw feed coal. To an increasing extent, this coal is fed to a storage and homogenization plant without further treatment. Homogenization then produces a consistent grain size and uniform contents of moisture, dirt, and volatile materials. The uniform quality of the coal feed makes possible a uniform product and optimal utilization of the washery capacity [26].

Figure 31. Homogenization of raw coal in a blending silo

Homogenization of the raw feed coal can be carried out in blending silos or on blending yards. Figure 31 shows the homogenization results of a silo. A critical factor in homogenization is the size of the storage location for containing one day's output.

In the washery the coal is first classified to ensure optimal utilization of the subsequent cleaning equipment for coarse coal and smalls. Normally the raw feed coal is screened off between 10 and 12 mm and subdivided into coarse raw coal and raw smalls. Such classification is carried out either on vibrating screens or on tensioned screens equipped with varying types of bottoms of perforated plate or tissue. The throughput for a unit may be as high as 1×10^3 t/h [27]. The raw coarse fraction is then subjected to wet mechanical cleaning, which completely removes adhering smalls and ultrafines by spraying.

Prior to cleaning of the raw smalls 0 – 12 (or 0 – 10) mm, the ultrafines are removed by a complex method. Normally an air separation method, e.g., dry classifying, or wet desliming on screens is used. Among the air separators, cyclone separators with mechanical dust discharge have proven to be most successful. These are designed for throughputs of up to 700 t/h. Vibrating separators are used in some exceptional cases where dust must be removed from all of the raw feed 0 – 150 (or 0 – 120) mm [28]. With some rare exceptions, the separator dust is added unscreened to the saleable products; in the future, however, an increasing proportion of the dust will need to be cleaned.

7.1.2. Wet Treatment

Cleaning of the raw feed is done by wet treatment in jigs and dense-medium separators, which separate according to differences in density or flotation (surface) properties.

7.1.2.1. Cleaning in Jigs

Almost all of the jigs used in Germany are of the air-pulse type or, in exceptional cases, of the wash-box type [29, 30]. They usually yield three products. Separation is accomplished by density, under the action of a pulsating flow of water. Pulsation may be applied either by a simple stroke or a superimposed double stroke.

The Batac jig with compressed air chamber underneath the bed proved to be the most successful machine. With such a system, all of the machine width, including the chamber width, is available for jigging. An electronic valve control

or a mechanical rotational valve is used to adjust the compressed-air load. Air pulsation coupled to the hydraulic inductive discharge controls enables the operator to modify the cut point by simply actuating a selector. This allows the cleaning of two different coal types successively in the same jig. The jigs usually accept coarse coal 10 – 150 (or 10 – 120) mm in diameter and smalls < 10 mm.

7.1.2.2. Cleaning in Dense-Media Separators

The coarse fraction is also cleaned by dense media, particularly in star-wheel extractors or inclined separators [31].

Whereas previously baryte, clay, ultrafine dirt, loess, and pyrite were used as dense media, the more recent equipment runs almost exclusively on magnetite and ilmenite. Selection of the dense medium depends on the method of regeneration (magnetic separation or gravity). The regeneration method also depends on the grain size of the dense medium.

A jig can be controlled by using either floaters or a layer of a given weight. It can also be fully automatic, controlled by gamma-ray counters. Dense-media equipment is controlled by maintaining the densities constant via automatic addition of the dense liquid. This adjustment can be set so precisely that it approximates separation by a true solution. While the cut point with dense-media cleaning is, in general, more precise than that with jigs, the latest achievements in jig cleaning have resulted in the widely expanded use of jigs within the Federal Republic of Germany because the coal normally is highly amenable to jig cleaning and because machine expenditure and costs are lower.

7.1.2.3. Cleaning by Flotation

Some of the raw coal feed in Germany is subjected to flotation. The diverging degrees of wettability of different mineral components allow cleaning of very fine particles by means of air bubbles. The bubbles are created by dispersion of the air feed in the dense medium; they remove the coal particles that have been rendered hydrophobic by flotation agents [32]. Flotation is applied to slurries if they contain an excessive percentage of mineral components so that their inclusion in the high-grade product is economically impossible.

Flotation plants consist of five to seven separate cells or flotation troughs with the corresponding number of stirrers. Each cell is between 5 and 14 m^3 and has a throughput up to 100 t/h particulate matter corresponding to 1000 m^3/h of pulp. Flotation is done either in one or two steps, with a flotation agent is of the collecting and foaming type. A ton of particulate matter requires 0.3 – 0.8 kg of flotation agent for the process.

7.1.2.4. Other Cleaning Methods

Cleaning on tables and in dense-media cyclones has been used in certain cases to reduce the sulfur content of the product and to obtain a coal extremely low in ash.

7.1.3. Dewatering

Moisture must be removed after wet cleaning [32 – 35]. There are static and dynamic methods. Among the dynamic methods are screen dewatering of nut-size coal and preliminary dewatering of small products on stationary screening tables or in refuse elevators. The static methods are being replaced by dynamic ones (centrifuge, vacuum, and pressurized dewatering) because of the demand for low final moisture content. The concurrent higher ultrafine and moisture contents in the raw coal have necessitated additional process steps.

Smalls are normally dewatered on vibrating screen centrifuges. Several improvements in their design – particularly the conversion from vertical to horizontal arrangements – have allowed high throughputs and easy repair and maintenance. Centrifuges with drum diameters of 1.3 m and rated capacities of 250 t/h (water-free) are the best. The smalls are dewatered down to 5 or 7 % at centrifugal forces of 80 – 100 g, depending on grain size distribution.

Coarse slurries are dewatered in pusher screens where the centrifuge forces (400 – 500 g) are higher than in vibrating screen centrifuges and where residences are considerably longer. Figure 32 shows a pusher screen. A first

(comparatively short) step provides preliminary dewatering and an even distribution of particles on the drum periphery. This is followed by the secondary dewatering step. Recent pusher screen designs have drum diameters up to 1.2 m with a rated throughput of coarse slurrying of more than 40 t/h. The coarse slurry is dewatered to 9 – 15 %, depending on grain size distribution.

Figure 33. Solid-bowl centrifuge
a) Solid bowl; b) Conveyor screw; c) Screen bowl; d) Enclosure

Drum filters with surface areas up to 120 m^2 and disk filters of up to 500 m^2 are available for ultrafine dewatering. With this equipment, specific feed rates of 100 – 800 kg m^{-2} h^{-1} (wf) and moisture contents of 18 – 28 % are attainable.

The flotation concentrate is also dewatered by means of a solid-bowl screen centrifuge where a solid-bowl section is followed by a cylindrical screen section, which dewaters the prethickened feed under favorable conditions independent of the particle concentration in the feed medium. Such a solid-bowl centrifuge is depicted in Figure 33. Flotation tailings are dewatered either by chamber filter presses or by solid-bowl centrifuges. More recently, screen belt presses have also been used. The selection of these alternatives depends on the desired moisture content of the waste.

7.1.4. Decantation and Thickening of the Process Water

Wet-type coal preparation plants involve a number of particle – water circuits where up to 6000 m^3/h medium are circulated. If the water is to be reused for further cleaning steps, the particulate matter must be removed from it as far as possible. Decantation units, which usually consist of circular thickeners with diameters up to 40 m, are used. Rectangular thickeners are used less often. Water circulation varies, depending on the mechanical equipment, and can be as high as 6 m^3 per ton of raw feed coal. Water consumption oscillates near 0.2 m^3/t feed for a closed circuit. It can rise to as high as 1 m^3/t feed if, e.g., salt content is excessive or if the flotation waste must be discharged to an external disposal site.

The decantation units are meant to bring about simultaneously a desirable degree of thickening for subsequent dewatering or cleaning procedures. Thickener outputs fluctuate between final concentrations of 120 g/L for flotation feed and 650 g/L for pusher screen dewatering. About 0.5 g of organic sedimentation accelerators are added per cubic meter to promote sedimentation for wash-water decantation.

7.1.5. Dosing and Blending

The products from coal preparation (nuts, dewatered smalls, air separation dust, flotation concentrate, and middlings, i.e., product that has a

high content of intergrown material) are stored separately in bunkers. The demand for nut-size particles has been declining, and they are reduced to < 10 mm diameter by impact or hammer mills. They then serve as a constituent of high-grade coals. The cleaned products are withdrawn from the bunkers and blended according to a set program. During this operation, the ash contents can be monitored or adjusted by automatic rapid-measuring instruments. The addition of those components that are highest in ash (air separation dust) is adjusted, depending on the measurements, so that the final product is brought to the desired ash content. Instruments for rapid and continuous measurement of moisture content will soon be introduced. Other mechanical equipment used for dose-feeding and blending includes filling-level indicators, dose-feeding devices, and belt weighers.

7.1.6. Removal of Pyritic Sulfur

Sulfur may be present in hard coal as elementary sulfur, sulfate, organic sulfur, or sulfide (pyrite).

Pyritic sulfur is removed by modern cleaning procedures [36, 37]. The raw coal is screened off at ca. 40 mm. The dirt of the > 40 mm product is removed in a jig. The jig floatings are reduced to < 40 mm, fed along with the < 40 mm product from sizing to a blending yard, and homogenized. The product is then cleaned in another jig; the coal and intergrowth of this step are reduced to a diameter of < 10 mm and fed to dense-media cyclones to yield, at low separation density, a raw coal low in sulfur. The intergrowth from the cyclone is reduced to a diameter < 3 mm and then classified in cyclones at 0.063 mm and subjected to secondary cleaning on tables. The < 0.063 mm product is then subjected to flotation. Dewatering of the intermediate products is done in vibrating screen centrifuges, pusher screens, and solid-bowl screen centrifuges.

7.1.7. Thermal Drying

Thermal drying is restricted to a few special cases in the treatment of coking and power station coals because the procedure involves high costs. The continuing increase of the ultrafine proportion, which is difficult to dewater, and the increasingly stringent quality demands necessitate more advanced dissociation and cleaning of ultrafines, as well as novel techniques of coal extraction, haulage, and treatment. These factors have led to increasing reliance on thermal drying in the aforementioned sectors [37].

Drum-type dryers are usually superior to the gas suspension dryers in terms of energy balance. The quality requirements for coals for coking and power stations require that only part of the coal volumes be dried to stay within the moisture tolerances required for the final smalls product. Less drying also reduces problems of dust.

7.2. Brown Coal Preparation

Brown coal is generally delivered without any preparation from the coal mines. Due to transport costs (high water content up to 60 wt %), the coal users have to be relatively close to the mines. The preparation of brown coal includes breaking, crushing, and screening as well as thermal drying. For decentralized supply of energy, fluidized-bed coal is produced for low emission fluidized-bed combustion (coal with a water content of about 16 wt %, grain size < 4 mm). Pulverized coal (water content about 11 wt %, grain size < 0.3 mm) is also applied in the cement and lime industries. Predried and fine-grained coal is used for briquetting, fine coke production, and montan wax extraction.

8. Agglomeration

Numerous industrial processes require coal in its coarse state for handling and transportation and as a feed for such thermal applications as combustion, gasification, iron ore reduction, and carbonization. However, highly mechanized mining operations, coal preparation, and beneficiation yield a high proportion of fines. Upgrading of such coal fines by agglomeration is frequently applied and considered [38 – 43].

The choice of agglomeration process and of a possible binder depends very much on the degree of coalification of the coal and the intended application.

The agglomeration ability of a coal is mainly influenced by its moisture-holding capacity, ash

content and composition, hydrophobicity, size distribution, and plastic or elastic behavior.

Fundamental coal agglomeration methods are grouped into

1) briquetting and extrusion [39, 43 – 47];
2) balling and tumbling [39, 41, 42], [48 – 51].

Coal briquetting is intended to turn fine-grained coal (< 6 mm) into a lump form. This conversion leads to a better manageable solid fuel especially for domestic heating. Briquetting is also necessary if coal is reacted in a fixed bed subjected to a gas flow (e.g., in fixed-bed gasification) and for lump or formed coke production from noncaking coal.

Regarding the temperature range, briquetting processes are subdivided into *cold briquetting* (< 100 °C) and *hot briquetting* processes (400 – 500 °C). The production of high quality briquettes by cold briquetting without binding agent is only possible with soft brown coal. Binding agents such as pitch, tar, and bitumen were formerly used for low volatile coals. Because of their carcinogenic effect (which is particularly pronounced if such binding agents are based on hard coal), they are being replaced by other binding agents, e.g., biomass materials (for example molasses). Hot briquetting is a less common method of compacting. Here, a caking coal in its softening range is used as the binding agent. Low sulfur emission briquettes can be produced by adding sulfur binding components such as milk of lime to reduce the sulfur dioxide emission during low- and medium-temperature combustion.

Balling of finely ground prepared coal generally smaller than 0.315 mm in particle diameter with 2 – 6 wt % of organic or inorganic binders has only recently evolved as a commercially viable coal agglomeration technique by using pelletizing disks designed for light bulk materials [41, 51, 52]. Both moist and dry pellets may be used industrially. Although the disk produces pellets of almost uniform size, tumbling in, e.g., rotary drums or mixers yields pellets of a wide size distribution. This mode of agglomeration is preferentially applied to subbituminous, bituminous, and anthracitic coals of both low and high ash contents, but predried lignites can also be pelletized [39, 48, 49]. Drying and thermal treatment of these pellets, however, cause severe cracking and significant losses in strength and stability.

Coal agglomerates must withstand mechanical and thermal treatment when used in industry. The type and severity of stress depend on the particular use and mode of treatment which mainly include transportation, drying, thermal shock, pyrolysis, gasification, and combustion [43, 46, 48]. Suitable procedures for the agglomeration step may be developed and selected from bench-scale simulation studies. Subsequent handling and thermal experiments with these agglomerates lead to a final, optimized product, which may be tested on a larger scale in pilot or commercial plants.

9. Coal Conversion (Uses)

The aim of coal conversion processes is the improvement of the fuel's utility value (e.g., production of briquettes and coke) and/or the transformation into other energy carriers or energy forms (e.g., electric power generation, gasoline production), or the production of products for nonenergetic use (e.g., synthesis gas, activated carbon).

Coal refining may be divided into three stages:

1) Mechanical conversion processes (e.g., crushing, screening, separating) and mechanical-thermal processes (e.g., drying, briquetting)
2) Thermochemical conversion processes (e.g., combustion, coking, gasification, direct liquefaction)
3) Carbochemical processes (e.g., processing of liquid coal reaction products) and gas treatment (e.g., cleaning, conversion)

The most important refining routes, the individual conversion processes, and some of the intermediates and end products are shown in Figure 34. The bold lines depict the most important routes worldwide. The thinner lines represent common routes with more local importance, and the broken lines show those that have no commercial applications at present.

By *thermochemical coal refining* coal can be converted into gaseous, liquid, and solid products and its energy content possibly into sensible heat. Product distribution and composition vary

Figure 34. Coal utilization and conversion processes

over a wide range as a function of the process conditions, especially the reaction atmosphere; but also temperature, pressure and use of catalysts have to be taken into account. These are also the parameters to subdivide the individual thermochemical coal conversion processes into combustion, gasification, liquefaction, and pyrolysis. But there are transitional ranges which make the classification of some processes difficult.

The large experience in industrial-scale coal conversion processes is increasingly exploited for energetic and nonenergetic uses of biomass, industrial residues, and waste material.

9.1. Pyrolysis

Pyrolysis (also called thermolysis) is the thermal decomposition of organic substances such as coal during heating to more than 300 °C in a oxygen-free atmosphere. It is the generic term for carbonization, coking, and devolatilization. It is also the starting reaction in gasification, combustion, and direct liquefaction.

The decomposition products of pyrolysis are the pyrolysis gas (mainly hydrogen, carbon monoxide, carbon dioxide, methane, and C_2–C_5 hydrocarbons), the liquid products (tar, oil, crude benzene, and water), and coke as a solid residue and main product. Depending on coal properties, different sulfur and nitrogen compounds are formed in the pyrolysis process.

The pyrolysis product distribution and composition are mainly determined by the coal type but can be influenced by process parameters such as heating rate, temperature, atmosphere, and pressure.

The *hydropyrolysis* process operates under high hydrogen pressure and leads to a high yield of gaseous and liquid products, especially BTX aromatics (benzene, toluene, and xylene). In

flash pyrolysis a very high heating rate is used (500 – 20 000 K/min), in order to increase the yield of gaseous and liquid products. *Plasma pyrolysis* is carried out with a high heating rate in a high-temperature plasma atmosphere (2000 – 5000 °C), particularly to produce acetylene. These special pyrolysis processes with extreme process conditions currently have no or only few commercial applications.

9.2. Carbonization and Coking

Low-temperature carbonization and coking involve heating of coal with the exclusion of air. This process removes the condensable hydrocarbons (pitch, tar, and oil), gas, and gas liquor, leaving a solid residue of coke. Low-temperature carbonization (up to 800 °C) and coking (> 900 °C) are differentiated by the final temperature. The two processes also differ sharply in the rate of heating of the coal and in the residence time in the reactor. These parameters have a direct effect on the product yields. Low-temperature carbonization produces fine coke and fairly large quantities of liquid and gaseous products, whereas high-temperature coking is used primarily for the production of a high-temperature lump coke for blast furnaces and cupola ovens. After the oil crisis of 1973, attempts were made to submit the coal used in power stations to preliminary low-temperature carbonization. The coal byproducts were then to be refined while the coke was used for firing. However, the process could not be made profitable.

high-temperature coking of coal is carried out entirely in batch-operated coke ovens, of which the majority are of the horizontal chamber type. The feedstock is a coking coal of given size composition. The coking properties depend chiefly on softening and resolidification temperatures and on swelling behavior. Coking takes place at 1000 – 1300 °C. The coking time of 15 – 30 h depends on the operating conditions and width of oven. The main product is metallurgical coke required for the production of pig iron. Metalurgical coke is characterized by its suitable size and high resistance to abrasion even under blast furnace conditions. Coke oven gas and liquid byproducts are also produced. In Western Europe, these byproducts influence the economy of coking and, therefore, are reprocessed.

Considerable technical improvements in coke production have led to greater cost effectiveness. They include mechanization and automation of oven operation, reduction of coking time and increase of specific throughput by the use of thinner bricks of higher thermal conductivity, and increased oven sizes.

Coking in horizontal chamber ovens is becoming increasingly difficult for the long term due to the deteriorating quality of coal feedstocks. Therefore, coking technology must be assisted with additives and auxiliary technology. Potential additives include petroleum coke, bitumen, and oil. Among the auxiliary technologies to be considered are the ramming operation, such as is used in Germany and some East European countries, and the various modifications of coal preheating, which are used in the United States and Japan.

Dry cooling of coke has found increased use in Western Europe to recover stored heat. For climatic reasons this technique has been used for a considerable time in the (former) Soviet Union. Dry cooling of coke leads to considerable savings in energy and pollution, especially when used in combination with preheating.

At the start of the 1960s, many countries considered developing a continuous production process for formed coke in expectation of a further worldwide increase in demand for coke for steel production. Numerous process developments, such as briquette coking or hot briquetting of a mixture of char and caking coal, have been demonstrated on an industrial scale. Even so, these processes have not been able to gain acceptance. This is partly because unexpected improvements in chamber coking have been realized and partly because the steel industry has been having difficulty for more than a decade, and thus, the anticipated shortage of coking coal has not yet occurred.

9.3. Coal Liquefaction

Coal liquefaction is a conversion process in which liquid fuels and liquid chemicals are obtained from solid coal. To this end, the H : C ratio has to be increased by raising the hydrogen content to about 10 – 15 wt %.

Coal liquefaction can be accomplished in two ways. In the first, called *direct liquefaction* or *coal hydrogenation*, the coal is suspended in suitable oils and treated either with hydrogen in the presence of a catalyst or with hydrogenating solvents to yield oil products and some unreactive residue (→ Coal Liquefaction, Chap. 3). In *indirect liquefaction*, coal is gasified (Section 9.4) to yield a mixture of hydrogen and carbon monoxide (synthesis gas) from which liquid products can be synthesized in one or more steps (→ Coal Liquefaction, Chap. 2). Both routes developed into industrial-scale processes during the 1930s and were extensively used during World War II in Germany. Currently, (indirect) coal liquefaction is employed on an industrial scale only in South Africa (Sasol plants I, II, and III). Further developments were initiated to the point of large pilot plant operation, mainly in Germany, the United States, and Japan. These activities reached their peak between 1975 and 1985, and have partly been continued up to now (→ Coal Liquefaction).

9.3.1. Direct Liquefaction (Hydrogenation)

See also, → Coal Liquefaction, Chap. 3.

Coal hydrogenation is a hydrogenating digestion of the coal molecule. Hydrogenation using a solvent brings about depolymerization at ca. 15 MPa and 430 – 460 °C to yield an asphalt-like product. This product can be deashed, e.g., by hot filtration, and it can serve as a boiler fuel or as a feedstock, e.g., for the production of high-quality carbon products. Many development schemes went on to further hydrogenation of the filtration extract in a separate stage and thereby produce a synthetic oil that can be distilled and refined into marketable products [53, 54].

Catalytic hydrogenation of coal by the prewar Bergius – Pier process usually requires a pressure of tens of megapascals and a temperature of 450 – 480 °C. These strong reaction conditions yield a light oil fraction that can be further refined.

New generation processes are closely related to the earlier German developments but surpass these by (1) increased selectivity and yield of useful liquid products, (2) by a considerable reduction in operating pressure to 20 – 30 MPa from ca. 70 MPa, (3) by increased volumetric reactor throughput, (4) by improved availability of the plant, and (5) last but not least, by conditioning the unreacted residue in such a way as to make it accessible to steam reforming for hydrogen production. Depending on coal type and technology, the yield of liquid hydrocarbons reaches usually 50 – 7 wt %.

Although direct coal liquefaction is suited for production of low-sulfur and low-nitrogen boiler fuels, it is more useful for producing synthetic crude oil, which can be refined into light fuel oil, gasoline, and diesel as well as chemical feedstocks by petrochemical processing. However, direct coal liquefaction has presently no industrial use due to the availability of comparatively inexpensive liquid fuels and chemicals obtained from petroleum.

9.3.2. Indirect Liquefaction

See also, → Coal Liquefaction, Chap. 2.

The synthesis of hydrocarbons from synthesis gas is called indirect liquefaction. This technology is also named *Fischer – Tropsch synthesis* after its discoverers. The synthesis of liquid fuels by this process requires a synthesis gas with a H_2 : CO ratio of about 1 : 2.5. This ratio can be influenced by gasification conditions and subsequent gas conversion (Section 9.4). A great variety of catalysts were developed for the production of several liquid hydrocarbons.

Another way for indirect production of liquid fuels is the two-stage *Mobil methanol-to-gasoline* (*MTG*) *process* (→ Coal Liquefaction, Chap. 2.3). The first stage is catalytic methanol synthesis from synthesis gas. The second stage includes the catalytic reaction of methanol to gasoline.

The coal-based Fischer – Tropsch process used in South Africa is set up downstream of Lurgi fixed bed gasifiers. In the Sasol I plant, two different Fischer – Tropsch process technologies are employed, the fixed bed ARGE process (Lurgi – Ruhrchemie) and the entrained-flow Synthol process (Kellogg – SASOL). The ARGE process produces mainly gasoline fuel oil and waxes, whereas the Synthol process yields a larger fraction of gasoline and low molecular mass products (methane and propene). The SASOL II and III plants, built in the late 1970s,

use only the Synthol process. On an energy basis, the total liquid product yield obtained by indirect liquefaction of coal in the Sasol II plant is ca. 32 %.

9.4. Coal Gasification

Systematic development of coal gasification began in the first half of the 19th century. A mixture of carbon monoxide and hydrogen was produced. This was generally used for chemical purposes, which remained the main application of coal gasification for nearly 100 years. Town gas for lighting, cooking and – very much later – also for heating, in many cases was obtained as a byproduct from coke oven operation (→ Coal Pyrolysis). However, coal or coke gasification was also employed mainly for peak shaving in large gas schemes and also for the supply of gas to industrial furnaces. These applications provided strong development incentives, e.g., the first pressurized coal gasification for the manufacture of town gas to be distributed over larger distances [55, 56]. Natural gas and mineral oil in large amounts and at low cost replaced gas manufactured from coal not only in the heating market, but also in the chemical industry in most countries. The oil price increase of 1973 – 1974, and the fear for supply shortages, triggered new interest in coal gasification as well as the increased use of biomasses and waste material for energetic purposes in recent years (→ Gas Production).

Gasification can be accomplished by reacting coal with oxidizing or reducing agents. Using oxygen (or air) and steam as gasifying agents yields water gas.

$$C + H_2O \rightarrow CO + H_2$$

To supply the energy for this endothermic reaction either the carbon is preheated (water gas) or exothermic combustion and gasification reactions run in parallel (producer gas):

$$C + \frac{1}{2}\,O_2 \rightarrow CO$$

$$C + O_2 \rightarrow CO_2$$

The composition chosen for the blast depends on individual process conditions and governs the carbon monoxide : hydrogen ratio of the product. Varying the steam : oxygen ratio in the blast is a very sensitive and convenient means of controlling the reaction temperature.

Gasification with hydrogen (hydrogasification) leads primarily to methane in an exothermic reaction.

$$C + 2\,H_2 \rightarrow CH_4$$

However, due to thermodynamic and kinetic restrictions hydrogasification is usually incomplete and produces a char residue. Thus, reductive gasification is considered as only a preliminary step in the complete gasification of coal. However, it is a very favorable step if a gas with a high heating value, e.g., substitute natural gas (SNG), is to be produced. Hydrogasification is also involved in most fixed-bed countercurrent-flow gasification processes, contributing to the methane content of the product. Several other reactions take place simultaneously, including the Boudouard reaction, complete combustion of carbon, and methane formation from carbon monoxide and hydrogen.

In coal gasification processes, it is necessary to optimize heat transfer, mass transfer, and chemical reaction conditions, and to handle large streams of solid and gaseous agents. Many varieties of coal gasification processes have been developed, reflecting compromises of the many constraints and conditions.

First consideration must be given to the intended use of the product gas:

1) a fuel gas, e.g., a clean boiler or turbine fuel
2) synthesis gas, for the production of commodity chemicals
3) hydrogen, for ammonia production or for energy purposes
4) reducing gas, for direct reduction of iron ore
5) a gas with a high heating value, e.g., SNG

A second, equally important, consideration applies to the available coal. Of particular importance are coal rank, grain size, caking properties, ash content, and ash melting behavior. Third, environmental regulations, site specific infrastructure, etc. have to be taken into account. Considering all these factors, a decision in favor of

fixed-bed, fluidized-bed, or entrained-flow gasification can be made.

In a *fixed-bed* gasifier, coal and blast are usually contacted in countercurrent flow. This leads to the splitting of the overall gasification reaction into several zones with favorable conditions for the various reaction steps involved. Fixed-bed gasification usually results in excellent carbon utilization and high efficiency. It is applicable to coals of all ranks. However, it requires lump, noncaking or weakly caking coal with a high ash softening temperature. The product contains tars and other liquid byproducts that complicate the gas treatment. Atmospheric fixed-bed gasifiers of various design are still occasionally found in small-scale industrial use. On a large scale, some Lurgi fixed-bed pressurized gasification plants are operating commercially, e.g., in the Republic of South Africa (Sasol I, II, and III) and in the USA (Great Plaines). A more advanced process is the British Gas/Lurgi slagging gasifier requiring specifically less steam and being not sensitive regarding ash softening temperature.

Fluidized-bed gasification, invented in 1922 by Winkler at BASF, has the advantage of fairly simple reactor design. However, overall reaction temperature is limited by the need to avoid ash agglomeration. Therefore, Winkler gasifiers operating at atmospheric pressure to produce synthesis gas were restricted to reactive fuels such as subbituminous coals or lignite. These gasifiers are in operation, e.g., in Germany and in India. Further developments successfully led to the applications of higher pressure (HTW-Gasification) [57, 58]; of higher temperature allowing for local ash agglomeration (U-Gas) [59, 60]; and of higher superficial velocity (Circulating Fluidized Bed) [61].

Entrained-flow gasification takes place in a flamelike reaction zone, usually at a very high temperature to produce a liquid slag. For economical operation, a high-standard heat recovery system is mandatory, but the product gas is free of methane, tars, etc., thereby considerably simplifying gas and water treatment.

Entrained-flow gasifiers of the Koppers–Totzek design operated at atmospheric pressure are used industrially in many countries to produce hydrogen or synthesis gas. Further developments of this process type are aimed at the application of elevated pressure. The available processes differ in the modes of heat recovery and of coal feeding. Dry coal feeding is applied in the PRENFLO [62], the Shell [63] and the GSP processes, whereas in the DOW/Destec [64] and in the Texaco [65] process a coal water mixture is fed to the gasifier. Preferably these gasifiers are applied in conjunction with coal based combined cycle power systems (→ Gas Production).

Apart from these well-established or recently introduced processes, further intense development is under way on existing processes, as well as on new concepts. Such new concepts as pressurized gasification in various modes, hydrogasification, multistage processes, slag bath and molten iron processes, and allothermal processes, e.g., using process heat from gas-cooled nuclear reactors, have been proposed and tested [66 – 71].

Some of the new development projects have been terminated or shelved because of the present availability of cheap mineral oil and natural gas. However, the long-term incentive of securing and diversifying the world energy supply is still valid. Environmental considerations may favor converting coal into a clean fuel gas that can be used either conventionally or in highly efficient technologies like fuel cells or combined cycle power plants. Furthermore, low-quality coals, which are located in remote places and are therefore not marketable as such, can be gasified and converted on site into transportable products such as commodity chemicals or hydrocarbons and thereby contribute to worldwide supplies. Moreover, principles and know how of coal gasification are going to be applied in gasifying biomass and waste, either solely or in combination with coal.

9.5. Coal Combustion

In combustion only the energy content of coal rather than its carbon or hydrogen content is exploited. Since combustion products usually represent useless waste, combustion is not classically considered a coal conversion or refining process but rather an energy conversion process. The main reaction in coal combustion is complete oxidation of the carbon and hydrogen content with atmospheric oxygen. The heat released is utilized either directly, e.g., for room heating or indirectly, e.g., via steam generation. Although overall chemistry of coal combustion is

principally quite simple, the actual mechanisms involved are fairly complicated. They depend on reaction conditions and on many fuel parameters including chemical composition, intrinsic reactivity, volatiles and ash contents, particle size, porosity and pore structure, mineral matter properties, etc.

Entrained-Phase Combustion. The standard process applied in large-scale units is entrained-phase combustion of pulverized coal. Finely ground coal is injected through a burner into the furnace where it is mixed with the combustion air. Combustion occurs in a flame as main reaction zone. In the largest units several burners fire into one furnace either in separate flames or they form a common fire ball in the center of the furnace. At the high temperatures prevailing, reactions are fast and mixing of oxygen and fuel becomes rate determining. Hence, a large number of sophisticated burner designs have been developed to optimize the balance between the processes involved, i.e., heat release, heat transfer, gas and particle flow, ignition of the incoming fuel, and completion of the burn-out in the after-flame zones.

A recent development (1997) aims at combustion of pulverized coal under pressure [72] to make possible combined cycles with increased power generation efficiency.

Fluidized-Bed Combustion. In fluidized-bed combustion crushed coal is burned in a bed of hot inert material (usually ash or sand), fluidized by the combustion air. In this way combustion takes place in the very closely controlled temperature regime of ca. 750 – 950 °C. The high amount of hot inert bed material allows to fire also low-grade high-ash fuels with good efficiency. Moreover, because of the low combustion temperature sulfur dioxide (released by combustion of the fuel's sulfur content) can be effectively captured simply by addition of limestone to the fuel.

Fluidized combustion has been realized also at elevated pressure on an industrial scale. Application of elevated pressure offers the advantages of significantly smaller sized combustors and the possibility of gas turbine operation [73, 74].

Combustion on a moving grate. The oldest and still widely used combustion technology is combustion of lump coal on a fixed or moving grate. These stokers are particularly well suited for small- to medium-size units and feature simplicity of operation and a very wide range of part-load operation at still high efficiency.

Since these combustion systems operate most efficiently only with fuels meeting specific qualities, one of the main development issues in coal combustion is, on the one hand, the design of burner/furnace systems that can process coals with a wider margin of specification limits and fuel blends. On the other hand, characterization of coals/coal blends for use in combustion systems is another field of intense research [75 – 77].

Besides combustion of the main constituents of coal also unwanted side reactions occur, leading to pollution problems such as formation of oxides of nitrogen and sulfur and the emission of particulates. For large combustion facilities add-on units like catalytic converters, scrubbers, and filters are widely installed to control emissions. Modern combustion systems employ intrinsic combustion modifications such as low-NO_x burners or two-stage combustion as more cost effective means of pollution control [78, 79].

The advent of high-performance computing equipment as well as powerful codes for the simulation of combustion processes rendered possible the development of combustor models that – with often fair or good accuracy – can predict the response of the respective system to changes in fuel or operating condition with respect to temperature distributions, gas flows and concentrations, burn-out and pollutant levels. In the 1990s rapid development in this field also led to an improved understanding of the detailed mechanisms involved [80, 81].

Concerns over excessive emission of carbon dioxide into the atmosphere that might lead to inadverted climatic changes (greenhouse effect) have raised the interest in co-combustion of coal and biomass and other nonfossil solid fuels. Coping with the problems involved in handling and reliably and cleanly burning these fuels (or fuel blends) forms a new challenge for combustion experts [82 – 84].

9.6. Nonenergetic Use of Coal

Like petroleum, coal can be used as a basic feedstock in the chemical industry. Corresponding coal conversion processes were developed on an industrial scale. However, because of the more costly technology, coal-derived liquid fuels and chemicals are more expensive than those obtained from petroleum refining. Therefore the commercial application depends on availability and price of the different fuels and the economic or political situation. As a result of present (1998) relatively low global prices for petroleum and natural gas, the nonenergetic use of coal is of more local importance or is applied for the extraction of special products. That situation will change in the medium- or long-term future, when the prices for petroleum and natural gas will increase due to supply shortage (petroleum and natural gas constitute only about one-third of the global fossil fuel reserves, about two-third consist of coal; the current consumption of fossil fuels is in inverse proportion).

Several coal conversion processes can be used for the nonenergetic use of coal. Crude gas from coal gasification (Section 9.4; → Gas Production) is aftertreated corresponding to the quality requirements of subsequent processes and can then be used, e.g., for ammonia and methanol synthesis, for the Fischer – Tropsch synthesis and oxo synthesis. Liquid hydrocarbons obtained in coal pyrolysis (e.g., in coking or carbonization processes) (→ Coal Pyrolysis) and coal liquefaction (at present without commercial application) (→ Coal Liquefaction) can be refined to various basic materials for chemical industries. Other coal-based products are montan wax, electrode carbon, carbon black, and carbonaceous adsorbents.

9.6.1. Extraction of Montan Wax

Brown coal extraction is a thermal material separation process. The montan wax obtained in this way is a multicomponent mixture, consisting in particular of long-chain aliphatic acids, their esters, and long-chain alcohols (→ Waxes, Chap. 3). Montan wax is solid under ambient conditions and melts at about 85 °C without decomposition.

Only special types of bituminous brown coal are suitable for montan wax production. Therefore, this process is only of local importance. The biggest coal extraction plant is in Amsdorf in eastern Germany with a present annual output of about 18 000 t montan wax (these are about 85 % of the world's capacity). Since the beginning of the 20th century montan wax from bituminous brown coal has been produced on an industrial scale in this plant. The bituminous brown coal is selectively mined and prepared by crushing, screening and thermal drying (grain size 0.2 – 3 mm, water content 14 – 16 wt %). Coal extraction is carried out with toluene as extracting agent (other organic solvents are also possible) at 80 – 90 °C in a continuous belt extractor. The solvent is thermally recovered; the extracted and almost solvent-free coal can be used as fuel.

About three quarters of the crude montan wax are bleached and used for a variety of purposes, e.g., for carbon paper, as release agent for plastics, ceramics and insulating materials, as paint additive, as impregnating agent for leather, and for the building and construction industry.

9.6.2. Coal Tar Chemical Industry

Coal tar and crude benzene formed as byproducts in the coking process are used as aromatic chemical feedstocks in considerable quantities. About 15×10^6 t of hard coal tar are annually obtained in the production of metallurgical coke. In the caking process ca. 3 wt % crude tar, ca. 1 wt % crude benzene and also ca. 0.3 wt % ammonia are produced from dry coking coal.

Benzene is extracted from crude benzene and can be processed, e.g., to plastics intermediate products such as styrene and phenol.

Coal tar is first distilled into different fractions. These are further processed by crystallization, extraction, and carbonization. Important products are pure aromatics and aromatic oils, phenols and heterocyclic compounds – which are important basic materials for pigments and dyes and for pharmaceuticals – and carbon black, used, e.g., for colored printing ink and as filling material for rubber.

Pitch is the tar distillation residue with a boiling range > 450 °C (about 50 wt % of coal tar). It is particularly used for electrodes and carbon fibers (→ Tar and Pitch).

9.6.3. Production of Carbonaceous Adsorbents

Carbonaceous adsorbents are divided into three groups: activated coke, activated carbon, and carbon molecular sieves. Carbonaceous adsorbents can be produced from both hard coal and brown coal (besides other raw materials). If the adsorption-relevant pore system is primarily formed by pyrolysis, the solid residue can be used as *activated coke* for flue gas cleaning or for waste-water purification. The next stage is the activation of coke by partial removal of carbon by gasification. Thereby the pore system is modified, and the specific surface can be increased considerably. The *activated carbon* produced in this way is the most important carbonaceous adsorbent. It is used for recovery of solvents and other recycling materials, drinking water treatment, etc. *Carbonaceous molecular sieves* are obtained if carbon is added by pyrolysis of hydrocarbons in the pore system after the activation process. In this way the size of micropores can be fitted to the size of certain molecules, and the adsorbent is applied for separation of air, methane, hydrogen from coke oven gas, etc.

Besides the adsorption properties of these carbonaceous materials, also their ignition behavior and their resistance to abrasion, which have to be taken into consideration for many applications, can be influenced by the production process (→ Carbon).

10. Transportation

The large amount of coal that is mined every year is a major commodity for the transportation industry and one that requires a significant capital investment. In the USA, ca. 50 % of the $700-800 \times 10^6$ t of coal produced per year is shipped by rail; 18 % is shipped by river barges; and the rest is handled by trucks, conveyor belts, and pipelines. The actual cost of long-distance shipping is usually quite modest, but the loading and unloading of the coal adds greatly to the total cost of shipping. In a typical surface mining operation, for example, coal is moved from the mine by truck or conveyor belt to a nearby preparation plant, where it is loaded onto a unit train for rail shipment to a utility or port facility. At the port it may then be loaded onto river barges or ocean-going bulk carriers.

Although some of the coal transported by *rail* is shipped at single-car or bulk rates, most is carried at lower rates in unit trains of up to 100 cars that travel continuously to a single destination and return. The unit train carries only coal and each car can carry up to 100 t. The cars are of either the bottom-dumping or roll-over type, and each car can be unloaded in 1.5 – 5 min in modern processing facilities, which have a capacity of 2000 – 6000 t/h.

The least expensive means of transporting coal is by *river barges*, whereby the cost is as low as $ 0.003 per kilometer. The barges have open tops and commonly hold up to 1000 – 1500 t each. They are moved in groups or tows of 20 – 30 barges powered by a single towboat. Although there can be some problems with delivery schedules due to congestion, the ease and economy of river transport are major factors in the location of many coal-burning utilities along inland waterways in the USA and in Europe.

In the USA, ca. 12 % of coal production is carried by *trucks*. Much of this is done at surface mines, where the coal is hauled from the working face to preparation plants. This is usually done with dedicated high-capacity vehicles; however, significant amounts of coal are hauled by trucks on public highways. *Conveyor belts* are also used for transporting coal from mines to preparation plants, as well as for short cross-country hauls of over 16 km to loading points. Because they are dependable and economical, conveyor belts are also widely used for in-mine coal transport.

Although > 80 % of the coal mined in the USA is used domestically as steam coal, some of the metallurgical coal production is shipped overseas. This coal is shipped in dry bulk carriers that can be loaded and unloaded in modern port facilities at rates of up to 100 000 t/h. These *ocean-going ships* are usually in the 60 000 t range, although some are larger. In addition, some smaller vessels in the 30 000 t range that are self-unloading are also in service. These ships have the advantage of being able to use a much greater number of ports.

The transportation of coal by *slurry pipeline* has been demonstrated to be dependable and economical, even though there are only a few such pipelines in use around the world. In this

technique the coal is reduced to a diameter of < 1 mm, treated with chemicals to prevent corrosion and improve flow characteristics, and mixed with water. It is then pumped as a slurry at a velocity of 1.5 – 2 m/s. The fact that pipelines can be built above ground or buried eliminates some environmental problems, but their high water requirements can be a serious drawback. Sustained delivery rates of > 600 t/h have been demonstrated.

11. Coal Storage

The use of any bulk commodity requires the storage of sufficient material to ensure efficient operations. In the case of coal, this requirement varies from a few days supply at the mine to a few months supply at a power plant. Although some covered storage in bins or silos is practical at mines and small operations, most of the larger volumes of coal are stored in open piles, where it is exposed to the air and precipitation. When coal is exposed to air, it loses moisture and begins to oxidize. This oxidation can degrade coal quality, and more importantly, it can cause spontaneous combustion that destroys the coal. The main coal properties that influence oxidation are particle size, pyrite content, and rank. Coal oxidation leading to spontaneous combustion is enhanced as the particle size decreases and as the pyrite content increases. Low-rank coals such as lignite and subbituminous coal are very difficult to store because of their strong tendency toward spontaneous combustion, and care must be taken even with the lower rank bituminous coals. Repeated wetting and drying also exacerbate oxidation. The continued oxidation generates more heat than can be dissipated, and this leads to hot spots, which eventually ignite.

In a stockpile even mild oxidation can lead to degradation of coal quality. For steam coals there can be some loss in calorific value, but in coking coals there can be a total loss of quality. The fluid properties can be destroyed, and the heat-transfer properties and coke production yields can also be reduced. The quality of coke made from oxidized coal is also seriously altered. The prime coke property, coke strength or stability, is reduced, and this can result in the loss of iron production in the blast furnace. Oxidized coal also increases the reactivity of coke and leads to higher coke consumption in the blast furnace. Because all of the effects of oxidation are undesirable, every effort should be made to prevent it.

The main steps to prevent oxidation involve limiting the access of air and protection from wind and precipitation. Stacking the coal to eliminate size segregation and compaction of the pile with earth-moving equipment to reduce pore space have proven helpful. Coating the pile with a sealant also helps protect it from air and moisture, although this may be expensive. Another costly but useful step is to provide the storage piles with some kind of wind protection. The wind not only enhances oxidation, but it also removes the fine particles from the coal pile and can thereby create environmental problems.

Another aspect of coal storage is the need to mix and blend the stockpile coal to homogenize the product coal reclaimed from it, so that a consistent, uniform product can be delivered to the plant. This can be a serious concern in cases where coal enters an operation from a number of sources. The usual way to solve this problem is to develop a bedding and blending system. A typical system consists of building a stockpile with long, thin layers of the various incoming coals and reclaiming the coal from the pile with vertical cuts across these layers. The key design factors are the variability of a target blending parameter such as ash or sulfur content and the desired degree of homogeneity. These are evaluated to determine the necessary pile parameters such as individual layer thickness.

12. Quality and Quality Testing

Because coal is so variable in its maceral and mineral composition, its suitability for a given use must be determined by a variety of tests. Although some tests such as chemical analysis are quite general in nature, others such as ash fusion are specific for particular uses.

12.1. Chemical Analyses

Although coal is composed of a large number of organic chemical components, no true standard organic chemical test exists for coal. The two

major kinds of chemical analyses used are the proximate analysis and ultimate analysis, which are standard tests defined by the International Organization for Standardization (ISO).

The proximate analysis consists of a determination of the moisture, ash, and volatile matter, and a calculation of the fixed carbon value. The *moisture* (ISO 331–83) is determined by heating the sample at 105 – 110 °C to a constant weight. The percent weight loss is reported as the moisture value. The *ash content* (ISO 1171–97) in this analysis is the incombustible residue after the coal is burned in air to a constant weight. The ash content is not a measure of the kinds or relative amounts of the minerals in the coal. The *volatile matter* content (ISO 562–98) is a measure of the amount of gas and tar in a coal sample. It is reported as the weight loss minus the moisture after the coal is heated at 900 °C for 7 min. The *fixed carbon* is not a distinct chemical entity. It is reported as the difference between 100 % and the sum of the moisture, ash, and volatile matter values. The standard tests defined by the American Society for Testing and Materials (ASTM) differ usually only in the amount of the sample and/or the heating rate and temperature conditions (ASTM D 3172–89). While the proximate analysis as described above is a rather simple assay of the chemical nature of coal, its value as a quality parameter is well established and is widely used in commerce.

The ultimate analysis consists of direct determinations of ash, carbon, hydrogen, nitrogen, sulfur, and an indirect determination of the oxygen. The ash is determined as in the proximate analysis, and because all of the values are reported on a moisture-free basis, moisture must also be determined (Table 11).

Table 11. Ultimate analysis, test standards

Test	ISO	ASTM D 3176–93
Carbon/hydrogen	609–96, 625–96	D 3178–93
Nitrogen	332–81, 333–96	D 3179–93
Total sulfur	334–92, 351–06	D 3177–93
Oxygen	1994–76	
Ash	1171–97	D 3174–93
Moisture	331–83	D 3173–92

Both proximate and ultimate analyses are reported in a number of different ways, and care must be taken to be certain of the method of reporting. On the "as-received" basis, the results are based on the moisture state of the coal sample as it was received for testing. With the "dry" basis, the results are calculated back to a condition of no moisture, and with the "dry, ash-free" basis, the results are calculated to a condition of no moisture and no ash. These calculations are done so that different coals can be compared on their inherent organic nature. The reporting basis (ISO 1170–77, ASTM D 3180) can cause significant changes in the values reported, and it is essential that a target value and the value of a sample in question be on the same basis.

Because some components of the minerals such as water from the clays and carbon dioxide from calcite are lost in the high-temperature ashing process, the ash value determined is less than the actual mineral matter in the raw coal. A number of corrections for this loss are in use, but the one most used in the United States is the Parr formula, where the corrected mineral matter is equal to 1.08 times the ash percentage plus 0.55 times the sulfur percentage. The average mineral matter factor for German Ruhr coals is 1.09. Results reported with this correction are considered to be on a dry, mineral-matter-free basis.

12.2. Mineral Matter

The mineral matter content of a coal is the actual weight percent of the minerals present. It is the best measure of the inorganic content of a coal, but it is difficult to determine. Determination of the mineral matter content or mineral matter factor follows a procedure which is described in the standard test ISO 602–83:

- Partial demineralization of a sample of the coal by treatment with hydrochloric and hydrofluoric acids under such conditions that the coal substance remains unaffected.
- Recording of the loss in mass of the coal due to the acid treatment and determination of the undissolved part of the mineral matter by ashing the partially demineralized coal.
- Determination of the iron content of the ash so that the pyrites present in the extracted coal can be calculated.

– Determination of the amount of hydrochloric acid absorbed by the coal substance.

No corresponding ASTM standard exists, however a procedure widely used in the United States is low temperature ashing ($< 150\,^{\circ}$C) with an oxygen plasma device. The X-ray diffraction analysis of the low-temperature ash is used to identify the actual minerals in the ash. Other techniques used to analyze the minerals are infrared spectroscopy, differential thermal analysis, electron microscopy, Mössbauer spectroscopy, and light microscopy for petrographic investigations. However, with present techniques it is impossible to accurately determine the amounts of the various minerals present in a given coal.

Although a large number of different minerals have been identified in coal, the four most common substance classes are clays, sulfides, carbonates, and quartz. The minerals get into the coal in a variety of ways. Some can be part of the original plant material itself. Silica (quartz) is present in some of the saw grasses of modern swamps, and similar types of plants are known from ancient swamps. Certainly much of the mineral matter is transported into the coal-forming swamp from the environment. Much of the clays and quartz minerals were brought into the coal swamp as clastic material in streams or in airborne dust. Most of the common minerals could be chemically precipitated from solution under conditions that can exist in swamps. Some minerals such as sulfides and carbonates can also be precipitated into cleats and fractures in coal after it has formed and coalified beyond the peat stage.

The presence of sulfur in coal is of great interest because of the problems it causes in utilization, especially air pollution. There are three commonly recognized forms of sulfur in coal. Sulfide sulfur is the sulfur tied up in, e.g., pyrite, FeS_2; it is determined by leaching with nitric acid. Sulfate sulfur is of minor importance and thought to be formed by the weathering of pyrite; it is determined by leaching with hydrochloric acid. Organic sulfur is that portion of the total sulfur that is organically bound with the various coal macerals; it is determined indirectly by difference. There also may be some minor elemental sulfur present in coal. The forms of sulfur are determined in accordance with the ASTM standard D 2492 or ISO 157–96.

The occurrence of pyrite in coal is of special interest because it is the only form of sulfur that can usually be removed by mechanical cleaning methods and because it is a major source of air and water pollution. Although some pyrite is formed by the chemical combination of the sulfur and iron that occur naturally in peat, most of the pyrite found in coal is thought to form from Fe(III) ions absorbed on clay minerals that are transported into coal swamps, and from sulfate ions that are introduced into the swamp in seawater. Marine water usually has about two orders of magnitude more sulfate ions than fresh water. In the swamp the ferric Fe(III) is reduced to Fe(II), which combines with the sulfur in the sulfate ions to form pyrite. Although this process is clearly not the only way of pyrite formation in coal seams, it is a good model for many U. S. coal seams, especially those in the Illinois Basin. In these seams it is reported [85 – 87] that both the total sulfur and pyritic sulfur contents are controlled by the nature of overlying rocks; they are both high under marine rocks and low under nonmarine rocks.

Pyrite can occur in coal in a number of forms such as single crystals, void fillings, irregular and dendritic masses, and framboids (raspberry-like clusters). The most significant forms are the more massive ones, which are easier to remove from the coal by washing, and the framboidal forms, which are more chemically active because of their high surface area. When pyrite is exposed to air and water, it oxidizes in a series of chemical reactions that generate sulfuric acid and cause acid mine drainage. In fact, the reaction of 1 mol of pyrite with air and water results in the generation of 2 mol of sulfuric acid.

12.3. Thermal Properties

The most widely used thermal property is the *gross calorific value* (synonymous superior calorific value, higher heating value), which is the specific energy of combustion for unit mass of a solid burned in oxygen under given conditions. The products of combustion are assumed to consist of specified gaseous products and liquid water (ASTM D 3286 & D 2015, ISO 1928–95). The *net calorific value* (synonymous infe-

rior calorific value, lower heating value) is defined as above, however all the water formed as reaction product remains in the vapor phase. For the classification of coals by rank (ASTM D 388–95) the gross calorific value is expressed on a moist, mineral-matter-free basis. In the "International Classification of Hard coals by Type" and for the use in steam generation the gross calorific value is expressed on an air-dried, ash-free basis (DIN 23003, Publication des Nations Unités Sales No. 1956 11E4). In many utility company contracts, coal is bought on the basis of total calorific value per unit mass.

13. Economic Aspects

13.1. World Outlook

Reserves. World proven recoverable reserves of coal are an estimated 519×10^9 t of hard coal and 465×10^9 t of brown coal (subbituminous and lignite) (Table 12). Proven reserves are those which geological and engineering information indicate with reasonable certainty can be recovered in the future from known deposits under existing economic conditions.

Table 12. Proven recoverable world reserves of coal as of end 2001 [88] (Quantity, 10^6 t)

Region or country	Anthracite and bituminous	Subbituminous and lignite
Africa and Middle East	56 881	196
North America	120 222	137 744
South and Central America	7 738	14 014
Asia	147 042	66 456
Former Soviet Union	97 362	132 613
Europe	47 234	74 289
Australia and New Zealand	42 583	40 079
Total	519 062	465 391

Production. Total production of hard coal (anthracite and bituminous) worldwide has increased clearly only since 2002. However, the individual regions of production have developed to different extents. For instance, production in Europe has been reduced, while the coal output of countries such as Australia, China, India, Indonesia, Columbia, and South Africa has increased, in some areas considerably. In 2003 production of hard coal reached 3.9×10^9 t (Table 13). World production of brown coal (subbituminous and lignite) has remained at the same level of 0.9×10^9 t since 1998 (Table 14). This amount yields approximately the same heat as 0.3×10^9 t of hard coal.

Table 13. World hard coal production in 2003 [89]

World total	3883.6	100

* Including brown coal
** Including lignito negro

Consumption. Approximately 20 % of the 3.9×10^9 t/a of hard coal used in the world is allocated to coking coal, and 80 % to steam coal. Virtually all brown coal is used in power stations. The largest growth in both production and consumption in the last years has been in the former Soviet Union, Australia and Asia.

Trade. Most coal is consumed in the regions of production. World trade in hard coal amounts to only 17 % of world production. Nevertheless, since some important consumer countries are without adequate resources of their own,

trade in hard coal has assumed worldwide proportions (Table 15). Australia, China, Indonesia, and South Africa are the main net exporting regions; Japan, Western Europe, South Korea, and Taiwan are the main importing regions. Brown coal is not traded over long distances.

13.2. Some Major Coal Producing Countries

13.2.1. China

Reserves. China accounts for ca. 12 % of the world's recoverable hard-coal reserves. Hard-coal reserves are concentrated in the north and northwest of the country. Substantial lignite deposits (about 11 % of the world's reserves) are distributed throughout the country.

Production. China is the largest producer in the world (2003: 1315×10^6 t hard coal including about 100×10^6 t lignite). Between 1996 and 2001 production decreased clearly, but increased again to the previous level recently.

Consumption. The vast majority of China's coal production is consumed in the country itself. Only a small portion is exported. About two-thirds of primary energy consumption is based on coal, of which more than half is used for electricity generation. The Chinese economy influences the global energy and raw-materials markets and is geared to further expansion.

13.2.2. United States

Reserves. The United States possesses economically recoverable hard coal reserves of ca. 116×10^9 t–one-fifth of total world reserves. For brown coal the respective figures are 134×10^9 t and nearly 30 %.

Production. The United States has maintained a high level of production for decades, producing one-fourth of the world's coal. Longwall mining accounts for an increasing proportion of underground coal production.

Consumption. Domestic coal consumption, which absorbs nearly 95 % of production, has varied little in the past few years, with power stations being the main consumers. Disregarding the traditional deliveries to Canada, coal imports, mainly from South America, are meanwhile higher than coal exports.

13.2.3. Former Soviet Union

Reserves. With 230×10^9 t of recoverable coal reserves, 97×10^9 t of which is hard coal, the former Soviet Union accounts for 25 % of total world reserves.

Production. The former Soviet Union still ranks third among world producers. The political changes were followed by major economic disruptions, which affected coal production in particular. Since 1998 hard coal production has increased continuously whilst lignite production has stagnated since 1995.

Consumption. The majority of production is consumed domestically. Exports to the EU and Asia show an increasing trend.

13.2.4. India

Reserves. India possesses ca. 15 % of world reserves of hard coal.

Production. Coal is the main source of energy and vital for India's economic development. Efforts to develop the industry have resulted in a steady increase in production to nearly 350×10^6 t of hard coal.

Consumption. Consumption doubled since 1984. Despite increased production, coal is imported, mainly from Australia. For the coming years a sustained upturn in growth with an impact also on the coal sector is expected for India.

13.2.5. Australia

Reserves. Australia possesses economically recoverable reserves of 43×10^9 t of hard coal and 40×10^9 t of brown coal, each representing 8 % of world reserves.

Production. Coal production has risen steadily in the last few decades (2003: 257×10^6 t) and is expected to do so in future.

Consumption. The high-quality coals found in Queensland and New South Wales are of value as steam and metallurgical coals, and most of production is for export. With 215×10^6 t Australia accounts for one-third of the entire global coal trade. In the world coking coal market it even holds a share of 60 %. Production from Western Australia, Victoria, and South Australia (bituminous and sub bituminous coal, lignite) is geared to local thermal electricity generation.

13.2.6. Republic of South Africa

Reserves. South Africa has recoverable reserves of ca. 50×10^9 t of hard coal, which at current production levels would last nearly 200 years.

Production. Following a phase of stagnation until 2002 production increased clearly only in 2004 (238×10^6 t).

Consumption. The slight increase in production in the last years was initiated by higher internal demand. Coal is the main primary energy for the generation of electricity (95 %). Exports are over 40×10^6 t/a.

13.2.7. Indonesia

Reserves. Indonesia has vast resources of high-quality accessible coal. In terms of tonnage, southern Sumatra contains the highest proportion, although much of it is lignite. The coal from Kalimatan includes some deposits of very high quality (low ash and sulfur, high volatile matter).

Production. Recently, annual production has risen significantly to meanwhile over 100×10^6 t.

Consumption. The national policy is to expand internal use; the target is for 80 % of electricity to be generated from coal-fired plants. But the main impulse to increase the production is the expanding export market. Indonesia has become the world's third largest exporter of coal (2003: 90×10^6 t).

13.2.8. Poland

Reserves. Polish recoverable coal reserves amount to 20×10^9 t of hard coal and 2×10^9 t of brown coal.

Production. Poland boosted its production for export reasons for a long period. In the mid-1980s government officials expected to increase hard-coal output to 205×10^6 t and its brown-coal output to 100×10^6 t by the year 2000. Instead, production in 2003 fell to 102×10^6 t of hard coal and 60×10^6 t of brown coal.

Consumption. Inland consumption decreased over the last decade and may decrease even further. In the meantime, Poland tried to maintain its exports. In 1984, when it was able to export 45×10^6 t Poland set its intermediate export goal at 42×10^6 t/a of hard coal. In 2003, exports reached only 20×10^6 t.

13.2.9. Germany

Reserves. Germany possesses nearly 7 % of the world's economically recoverable coal reserves.

Production. Output of hard coal has fallen from a peak of 150×10^6 t in 1957 to 29×10^6 t in 2003 and further reductions are planned. Brown-coal production dropped with the closure of mines in the eastern Länder. Nevertheless, with ca. 180×10^6 t, Germany is by far the largest producer of brown coal in the world.

Consumption. The majority of the hard coal (65 %) and nearly all of the brown coal is channeled into the generation of electricity. The second largest consumer is the steel industry. Following the decline of indigenous production, hard-coal imports have steadily increased (2003: 35×10^6 t).

13.2.10. Columbia

Reserves. Figures on hard coal reserves vary widely.

Production. As a result of growing demand for exports production has been expanded significantly over recent years (2003: 48×10^6 t).

Consumption. The major share (2003: 46×10^6 t) of production is exported. Columbia has become an important supplier of steam coal for the European Union and the USA.

1. Introduction

Coal liquefaction is a general term used to describe a process in which a portion of the organic coal substance is converted to liquid products. In the widest sense this includes liquids extracted by solvents. Waxes and resins have been produced commercially by extracting certain peats and low-rank coals with solvents, such as benzene or benzene – methanol mixtures [1]. Solvent extraction has also been used extensively in research on coal structure [2], [3].

More specifically, coal liquefaction involves producing liquids by chemically altering the coal structure and increasing the content of hydrogen relative to carbon. At the same time, nitrogen, sulfur, oxygen, and mineral matter are removed. Compared with other fuels (see Table 1), coal is particularly low in hydrogen. The hydrogen consumed in producing liquids of increased hydrogen content and in removing heteroatoms represents a large part of the cost of coal liquefaction.

Liquefaction methods can be classified as pyrolysis, indirect liquefaction, and direct liquefaction. In *pyrolysis* (→ Coal Pyrolysis), coal is converted at a temperature above 400 °C in a nonoxdizing atmosphere to gases, liquids, and char. The solid char is usually the main product. Liquid yields can be increased by employing a hydrogen atmosphere and by operating under conditions where the volatile products are rapidly diluted to minimize secondary reactions.

In *indirect liquefaction* (see Chap. 2), coal reacts with oxygen and steam at high temperature to produce a mixture of carbon monoxide and hydrogen (synthesis gas), which can be catalytically converted to liquid products. The best-known process, the Fischer – Tropsch (FT) synthesis, produces a mixture of gaseous, liquid, and solid (waxy) hydrocarbons. Other processes of growing importance are methanol syntheses and dimethylether (DME) production, which can offer a more selective route to fuels and chemicals [4–10].

In *direct liquefaction* (see Chap. 3), coal reacts at elevated temperature and pressure with gaseous hydrogen and a solvent that is a hydrogen-donor. Conversion to liquids can be realized with or without added catalysts. According to the conditions chosen, the principal products can be high molecular mass fuels, distillate fuel oils, gasoline, or chemical feedstocks.

The products of both indirect and direct liquefaction have a higher energy content than coal. Coal typically contains 60 wt % of the heating value of the liquefied products. The liquids produced by the two methods are very different in chemical composition. Synthesis gas conversion processes give saturated hydrocarbon liquids, whereas the products of direct liquefaction are highly aromatic. These chemical differences affect the end use. Indirect liquefaction

Table 1. Composition of selected fuels

Fuel	Element, wt %					H : C
	C	H	O	S	N	
Anthracite	93.0	3.1	2.4	0.7	0.8	0.4
Bituminous coal	78.1	5.5	10.0	5.3	1.2	0.8
Crude oil	86.0	11.2	0.6	1.6	0.5	1.6
Fuel oil	86.0	13.3	0.1	0.2	0.1	1.8
Gasoline	85.0	14.9	0.0	0.1	0.0	2.1
Methane	75.0	25.0	0.0	0.0	0.0	4.0

provides high-quality diesel fuel and intermediates for olefin production; direct liquefaction yields high-octane gasoline and excellent feedstocks for aromatic chemicals [11–14]. A hybrid plant concept where both direct and indirect technologies are sited at the same location may have some considerable merits [9], [10].

1.1. Commercial Development

Direct and indirect liquefaction have both been used commercially to produce liquids from coal. The first developments took place in Germany during the 1920s and 1930s. The original Bergius process was developed and modified by I. G. Farbenindustrie. The first module of a commercial plant was started up at Leuna in 1927. Indirect liquefaction was commercialized by Ruhrchemie, which built a plant in 1936 to produce 1000 t/a of liquids by the Fischer – Tropsch synthesis. During this same period, Imperial Chemical Industries (ICI) began work on the hydrogenation of bituminous coal at Billingham-on-Tees (United Kingdom), which led to the commissioning, in 1935, of the only commercial coal hydrogenation plant to be built in that country. The plant was originally designed for an output of 100 000 t/a of liquid fuel, which was later increased by 50 %. The plant operated until 1958.

Intensive efforts in Germany, before and during World War II, led to the construction of large-scale plants to supplement limited indigenous petroleum resources. In 1943, 12 plants were producing liquids by the hydrogenation of coal or coal tar and 9 plants by the Fischer – Tropsch synthesis. Liquids produced from coal by various processes reached a maximum output of over 5×10^6 t/a in 1944. Hydrogenation processes were the biggest producers, attaining a production rate of 3.25×10^6 t/a. Liquefaction by Fischer – Tropsch synthesis was comparatively small at 0.58×10^6 t/a. Coal-derived liquid fuels supplied all of Germany's aviation gasoline and were a major source of motor gasoline, diesel fuel, fuel oil, and some lubricating oils. After the war, three plants continued to operate in the German Democratic Republic until 1965 [5], [15–17]. Kieselguhr supported mixtures of cobalt and thorium oxide was the "standard" catalyst for the German Fischer – Tropsch process using tubular fixed-bed reactors [18].

German efforts laid the foundation for all later research and development. A commercial indirect liquefaction process was established in South Africa by South African Coal, Oil, & Gas Corp. (SASOL) using Fischer – Tropsch technology. The first plant, SASOL I, was brought on stream in 1955 with a rated capacity of ca. 800 m^3/d. Since then two more plants have been put into operation, SASOL II in 1980 and SASOL III in 1982. Each plant has a capacity of ca. 8000 m^3/d. South Africa, which has large coal reserves and no oil, adopted indirect coal liquefaction in order to become independent of petroleum imports [5], [8], [19].

All Fischer – Tropsch reactors at Secunda (SASOL II and SASOL III) were replaced by SASOL Advanced Synthol reactors during 1998 and 1999. As a result of this and other technology improvements the capacity of these plants has increased by about 20 % while simultaneously decreasing operating costs.

The technologies used to convert synthesis gas derived from natural gas to liquid products can in principle also be applied to coal-derived synthesis gas. For example, the SASOL Synthol technology first used with a coal-based plant is also used with synthesis gas derived from natural gas. Two other examples of natural gas-based commercial operations are the

Shell Middle Distillate Synthesis (SMDS) process at Bintulu, Malaysia with a capacity of about 2000 m^3/d [20] and the Mobil technology used for a plant in New Zealand with a capacity of about 2700 m^3/d [21]. The SMDS process uses fixed-bed Fischer – Tropsch reactors similar to those used previously in Germany and by SASOL, but with a more advanced supported cobalt catalyst. The New Zealand plant converts the synthesis gas to methanol and the methanol can then be converted to gasoline using the Mobil MTG (methanol-to-gasoline) process.

The commercial viability of coal liquefaction rests with the overall economy of the process. The conceptual design and economic evaluations performed on the direct liquefaction process in the early 1980s indicated that the price of equivalent crude oil from coal was above $ 50 per barrel. Economic evaluations performed by Bechtel Corporation and Amoco Oil Company (1992 – 1993) indicate that, under the operation conditions in the Catalytic Two-Stage Liquefaction (CTSL) process demonstrated at Willsonville, Alabama, the price of equivalent crude oil produced by direct liquefaction would be about $ 33 per barrel. Advanced liquefaction technologies will result in further reduction in the cost of coal liquids to the level of $ 20 per barrel so that may compete with the cost of petroleum crude by the early 2000s [10].

In 1997, China signed agreements with three countries, the state government, of Nordrhein – Westfalen, Germany (IGOR$^+$ process), Hydrocarbon Technologies Incorporation (HTI) of the United States, and New Energy and Industrial Technology Development Organization (NEDO) of Japan (NEDOL process), to execute feasibility studies for the construction of a direct coal liquefaction plant in China [22–25]. China has changed a net oil importer from an exporter since 1993. Coal liquefaction is an important way for ensuring energy supply according to China's current conditions, it is of practical significance particularly for the provinces with abundant coal and deficient oil resources.

In 1999, NEDO of Japan exchanged a memorandum of understanding on a feasibility study for the construction of a direct coal liquefaction plant, based on the Improved Brown Coal Liquefaction (BCL) process, at the request of the Agency of the Assessment and Application Technology (BPPT) of Indonesia [26]. Indonesia will become a net oil importer in the early 21st century, because of the increasing domestic oil consumption by the recent rapid economic growth. Liquefied oil from brown coal will effectively replace crude oil as a transportation fuel, and thus reduce Indonesia's dependency on imported oil.

These current feasibility studies for Asian countries, collaborated with Germany, the United States, and Japan (see Table 2), may lead to the commercialization of the direct coal liquefaction technology in the early 21st century.

These cases all represent government decisions to supply or underwrite most of the enormous capital requirements. Under normal peacetime conditions, coal liquefaction cannot complete with petroleum and is unattractive to private industry [5]. A notable exception is a privately financed Tennessee Eastman (USA) process for converting coal to acetic anhydride via the production of methanol from synthesis gas. The plant came on stream late in 1983 and gasifies 900 t/d of coal [6].

1.2. Historical Background

The events of major importance in the direct and indirect liquefaction of coal are as follows:

Direct Liquefaction

1869: Berthelot discovered that coal can be converted to oil by chemical reduction [15], [16].

1911: Bergius demonstrated the noncatalytic conversion of coal to heavy crude oil by using a solvent and hydrogen pressure [15], [16].

1925: I. G. Farbenindustrie demonstrated the first large-scale catalytic hydrogenation of coal [15].

1926: I. G. Farbenindustrie modified the Bergius process from one to two reactor stages for gasoline production [15], [16].

1927: I. G. Farbenindustrie started the first module of a commercial liquefaction plant at Leuna, Germany [15], [16], [27]. Pott and Broche initiated research to produce high molecular mass coal extract by using an H-donor solvent under mild

Table 2. Feasibility studies in Asian countries

conditions; the plant was built at Welheim, Germany (capacity 26 000 t/a) and operated from 1938 to 1944; some of the extract was used as hydrogenation feedstock [2], [15], [27].

1935: ICI commissioned a liquefaction plant in Billingham, England (original capacity 10^5 t/a); the plant was closed in 1958 [15], [27].
Semicommercial plant was built in Lievin, France (capacity 15 000 t/a). Two coal tar hydrogenation plants were built in Italy (combined gasoline production 24 000 t) [15], [16].

1939: Semicommercial liquefaction plants were built in Manchuria and Korea; both were subsidized by the Japanese government; success was limited [15].

1943: Total of 12 German hydrogenation plants were in operation; 9 in Germany, 2 in Poland, and 1 in Czechoslovakia (max. output 5×10^6 t in 1944) [15], [16], [27].

1949: The United States Bureau of Mines operated a semicommercial plant (50 t/d), based on German technology, in Louisiana, Missouri; the plant was closed in 1954 [15], [16], [27].

1952: Union Carbide developed a coal hydrogenation plant (300 t/d) at Institute, West Virginia for chemicals production; the plant was closed in 1956 [15], [16], [27].

1963: Consolidation Coal Co. developed Consol Synthetic Fuels (CSF) process and investigations continued to 1972; the process involved extraction followed by catalytic hydrogenation; 20 t/d plant at Cresap, West Virginia operated from 1966 to 1970; success was limited and the project was terminated [28], [29].

1963: Consolidation Coal Co. studied molten salt catalyzed liquefaction until 1968; the process involved use of large amounts of molten zinc chloride catalyst to selectively produce distillates; development was resumed in 1975; technical problems have limited progress [28].

United States (developments following formation of OPEC in 1973)

1973: Dow Chemical developed a process using disposable catalyst in a single-stage configuration; high dispersion of molybdenum catalyst was achieved by introduction in the form of an emulsion, allowing operation at low concentration; process was investigated to scale of 90 kg/d; it is not believed to be currently pursued [30].

1974: Chevron Research Co. began research that led to development of a two-stage process, first publicly reported in 1982; thermal liquefaction in the first stage was followed by catalytic hydroprocessing in the second; direct feed of effluent from the

first to the second reactor was claimed to minimize condensation of thermal products; it was scaled to 6 t/d; it is not believed to be currently pursued [31].

1974: Pittsburgh Energy Research Center has developed a catalytic process since 1967 that employed turbulent flow of coal-oil slurry through a fixed-catalyst bed; the operation involved 22 and 180 kg/d units; a proposed 8 t/d pilot plant has been terminated [28], [29].

1974: Gulf Oil operated a solvent-refined coal (SRC) 50 t/d pilot plant at Fort Lewis, Washington until 1981; a single-stage process to produce coal extract by non-catalytic reaction with solvent under hydrogen pressure was used; development was started in the 1960s; a later process variant SRC II was explored from 1977 to maximize distillates [19], [28], [29].

Southern Company Services operated and managed a 6 t/d SRC plant at Wilsonville, Alabama; development was in SRC-I mode to 1981; in 1981 the plant was modified to a two-stage process by addition of catalytic hydrotreater; plant is still in operation [19], [28], [29], [32].

1980: C-E Lummus Co. began operation of a process development unit to study two-stage liquefaction; research dates to 1976; the process combines a short residence time thermal dissolution stage with catalytic hydrotreatment of the higher boiling products in an ebullated-bed reactor; before the second stage, solids are removed by using a light solvent to promote separation and gravity settling; the unit operated until 1984 [33].

1980: A 200 – 600 t/d H-Coal plant at Catlettsburg, Kentucky was operated from May until August, 1982; the unit employed a single-stage ebullated-bed catalytic reactor. Since 1963 Hydrocarbon Research has developed pilot units (up to 3 t/d) using basic concepts derived from H-Oil process [28], [29], [34].

Exxon donor solvent plant (250 t/d) was in operation at Baytown, Texas until August, 1982; the single-stage process used donor solvent that was hydrogenated in a separate reactor; since 1966 Exxon has developed pilot units up to 1 t/d [28], [29], [35].

1982: DOE and the Electric Power Research Institute began developing and testing the two-stage liquefaction process at the 5.5 t/d facility in Wilsonville, Alabama. Two-stage liquefaction went through several process configurations before focusing on close-coupled catalytic two-stage liquefaction. Simultaneously, HRI performed bench scale development (25 kg/d) of close-coupled catalytic two-stage liquefaction [10], [36].

1983: The Wilsonville process development unit was the only remaining US test facility to allow proof-of-concept scale development of direct liquefaction. Operations at this unit ceased in 1992. HRI is now operation a 2.7 t/d unit in Lawrenceville, New Jersey, to continue the development of the direct liquefaction process at a proof of content-scale [36].

1992: Economic evaluations were performed by Bechtel Corporation and Amoco Oil Company (1992 – 1993). Under the high space velocity operating conditions demonstrated at Wilsonville, the price of equivalent crude oil produced by direct liquefaction would be about $ 33 per barrel. If steam reforming of natural gas were used instead of coal gasification for hydrogen production, this price would be reduced to about $ 31 per barrel [10].

1997: HTI signed an agreement with Shenhua Clean Coal Technology Development (SCCT) and China Coal Research Institute (CCRI) to execute a feasibility study for the construction of a Direct Coal Liquefaction plant in China, one of the major projects in China's tenth five-year plan. The project is to built a mine-mouth liquefaction plant (12 000 t/d) using coals (bituminous coals) produced in the Shenhua coal-field in Northern Shaanxi Province and Inner Mongolia near Baotou City. The HTI Coal Process consists primary of two backmixing reactor stages utilizing a proprietary dispersed superfine iron catalyst (GelCat) plus a fixed-bed in-line hydrotreater. The process operates at a pressure of 17 MPa and reactor temperatures in the range of 400 – 460 °C. Phase-l

is a preliminary feasibility study that involves a bench-scale continuous flow unit (CFU) test (30 – 50 kg/d) at HRI and a preliminary economic evaluation and local economic data for the plant. Phase-2 consists of a process development unit (PDU) scale test and a more in-depth economic analysis. The results of the feasibility study will be issued by 1999 – 2000 [22].

Federal Republic of Germany

1976: Bergbau-Forschung operated a 0.5 t/d pilot unit in Essen; the single-stage process used disposable iron catalyst, and was based on the original German process modified to operate at lower pressure by excluding liquids that could not be distilled from the recycle stream; the process is currently in operation to provide support for a 200 t/d plant at Bottrop [5], [37], [38].
Saarbergwerke operated a 0.5 t/d plant at Reden (and, since 1980, a 6 t/d plant at Völklingen); the process configuration was similar to that at Bergbau-Forschung [5], [38].

1978: Rheinische Braunkohlenwerke operated a 0.25 t/d unit at Wesseling for development of brown coal liquefaction; the process was similar to Bergbau-Forschung [38], [39].

1981: Ruhrkohle – Veba Oel commissioned a 200 t/d plant at Bottrop; scaleup was based on pilot unit at Essen, and is currently in operation [37].

1984: The integrated refining concept was initially developed in the PDU at Deutsche Montan-Technologie (DMT), and subsequently up-scaled in the 200 t/d Bottrop coal oil plant in 1985 – 86. Here it was successfully demonstrated through 5000 operating hours until the end of the test series in May 1987 [24].

1987: Ruhrkohle – Veba Oel successfully completed their test runs in the 200 t/d Bottrop Coal Oil Plant, which was subsequently modified to permit hydrogenation of vacuum residues from crude refining. Since 1989, the spectrum of feedstocks had been steadily extended to other chemical residues, e.g., used solvents, waste oil, spent charcoal, and polychlorinated biphenyls.

1992: Coprocessing test runs with mixed waste plastics were started. In 1995, the rather deficit-ridden hydrogenation of vacuum residues was abandoned. In future, only waste plastics will be converted at a rate of 80 000 t/a [24].

1995: Coal-based tests, which were continued in a PDU jointly operated by RAG Umwelt Rohstoffe GmbH (RUR) and DMT to provide technical support and process optimization during the test runs performed in the 200 t/d Bottrop Coal Oil Plant, were accomplished.

1997: The PDU was reactivated to support the work of a feasibility study on a hydrogenation plant to be set up in Yunnann, People's Republic of China. Process basis shall be the test runs on Xianfeng coal (lignite) performed in the proven PDU at the end of 1997 and beginning of 1998. Coal feed stock is a lignite with a carbon content near 70 %. The feasibility study is scheduled for presentation in Beijing in August, 1999 [24].

Japan

1974: The government established the national energy strategy, "Project Sunshine," with imported oil to be supplemented by products from coal [40].

1980: New Energy Development Organization (NEDO) centralized research and development [40].

1981: NEDO decided to construct a 50 t/d plant for brown coal liquefaction in the Latrobe Valley, Australia; the plant, currently under construction, will utilize a two-stage process, using disposable iron catalyst in the first stage and a fixed-bed catalytic reactor in the second stage [41].

1983: Three separate pilot scale processes for bituminous coal liquefaction were integrated into a single development project, using a two-stage configuration, similar to that planned for brown coal liquefaction; the 250 t/d plant is in the design stage [40–43].

1984: Design of a 250 t/d pilot plant was started in 1984, but the plant capacity was reduced to 150 t/d in 1987 [44].

1985: The PSU project started and its operation has been conducted by Nippon Steel, Mitsui SRC Development, and Nippon Coal Oil (NCOL) at Kimitu, Chiba since 1989. The adaptability of various kinds of coal (subbituminous and bituminous coals) and operating conditions were studied and the mechanism of coal liquefaction was being investigated. Improvement of the quality of coal liquid and economic optimization of the NEDOL process were performed until March 1999. The cumulative operation time is ca. 26 000 h using nine types of coal. The operation of a 1 t/d PSU has been carried out for supporting the operation of 150 t/d pilot plant using the same coals and same operation conditions as for the pilot plant since 1994. A series of the examination for expanding the range of applicable coal rank in the NEDOL process was implemented with Adaro, Ikeshima and Yilan coal; the applicable range of carbon content is 73 – 83 wt % [23], [45].

1985: A 50 t/d pilot plant for brown coal liquefaction at Morwel in the Latrobe Valley, Australia was successfully operated from June, 1985 until October, 1990. The Brown Coal Liquefaction (BCL) process has been developed by Nippon Brown Coal Liquefaction Co., Ltd (NBCL) which consists of five companies: Kobe Steel, Mitsubishi Chemical, Nissho Iwai, Idemitsu Kosan, and Cosumo Oil. This project was implemented as the national energy project between the Australia and Japanese government. A 0.1 t/d PDU has been operated at Kobe since 1981 to obtain basic data and to support the operation of a 50 t/d pilot plant. The conceptual design of a demonstration plant and follow-up study were continued until 1993 [46].

1991: NCOL has carried out the design, construction, and operation of the 150 t/d pilot plant of the NEDOL process under the support by NEDO since 1984. Design of a 150 t/d pilot plant was completed, followed by the construction work at Kashima, Ibaragi until June in 1996 [44].

1993: NBCL completed all programs related to the pilot plant experiments, and Takasago Research Laboratory (TRL) was established in Takasago works of Kobe Steel Ltd. to improve the reliability, the economics, and the energy efficiency of the BCL process and to promote the international collaboration on coal liquefaction [46].

1994: New R&D on the improvement of coal liquefaction technologies was started as one of the "New Sunshine Projects" supported by NEDO. Development of improved BCL process was carried out at TRL by using a 0.1 t/d bench scale unit (BSU) until March 1998. Use of a highly dispersed limonite catalyst improves oil yield and process reliability. The quality of recycle solvent and product oils are improved by the use of an in-line hydrotreater. An applicability study on direct coal liquefaction of Banko coal in Indonesia was simultaneously implemented under the Memorandum of Understanding for the research collaboration on coal liquefaction between NEDO and the Agency of the Assessment and Application Technology (BPPT) of Indonesia [26], [46].

1997: The operation of the 150 t/d pilot plant was started in March and continued for two years until September 1998. During the five operation runs, three types of coal with different ranks (Tanito Harum and Adaro coals in Indonesia and Ikeshima coal in Japan) were liquefied without serious problems [44], [47]. Japan International Cooperation Agency (JICA) signed an agreement with China Coal Research Institute (CCRI) to execute a feasibility study on direct coal liquefaction in China. Liquefaction of Yilan coal was performed by using a 1 t/d PSU to support the work of the feasibility study on the direct coal hydrogenation plant to be set up in Helong Jin, People's Republic of China. Feed stock coal is a subbituminous coal with a carbon content near 79 % which is ranked between Tanito Harum and Ikeshima coal. This feasibility study has been completed by the end of 1999 [23], [45].

1998: The R&D activities of NBCL since 1981 were successfully completed in March

and succeeded by the Takasago Coal Liquefaction Center (TCLC) in Kobe Steel Ltd. [46].

1999: NEDO signed an agreement with Shenhua Clean Coal Technology Development (SCCT) to execute a feasibility study on the liquefaction of Shenhua coal Shaanxi in China. Liquefaction tests were performed by using a 1 t/d PSU to support the work of the feasibility study on the construction of the coal liquefaction plant. This feasibility study has been completed by March 2000 [23], [45].

1999: NEDO also exchanged a Memorandum of Understanding on the feasibility study for a direct coal liquefaction plant at the request of the Agency of the Assessment and Application Technology (BPPT) of Indonesia. Along with the collaborative activities, the feasibility study was conducted by Kobe Steel, Ltd. supported by NEDO. The major objective of this study is to ascertain the suitability of Indonesian low-rank coal (lignite) for the use with the improved BCL process through a selection of plant location, a conceptual design of a commercial plant followed by a financial analysis. This feasibility study is scheduled for three years until March 2002 [45], [48].

United Kingdom

1976: The National Coal Board (NCB) investigated two liquefaction processes at Stoke Orchard, Gloucester; in one, coal was extracted in a heavy solvent without hydrogen or catalyst, and after filtration, the extract was catalytically hydrocracked to distillates; in the other, coal was extracted in an aromatic solvent under supercritical conditions, with extract considered as a feedstock for hydrocracking; both processes were developed to a scale of 50 kg/d and plans were made to build two 24 t/d pilot plants; the construction of a 2.5 t/d unit using a liquid solvent extraction process was planed [5], [16], [48], [49].

1985: The next stage in the development of the NBC's Liquid Solvent Extraction (LSE) process was to design, build and operate a 2.5 t/d process development pilot plant. This project was approved in October by BCC's Board and agreements reached with the Department of Energy and the EEC. Ruhrkohle Oel und Gas GmbH and Amoco corporation joined the project in 1987 and 1991, respectively [50].

1992: A 2.5 t/d pilot plant (LSE process) was operated until 1995 at Point of Ayr, North Wales. Point of Ayr coal (bituminous coal) was chosen as the standard coal for use in experiments from 1981 on [50].

Indirect Liquefaction

1902: Sabatier and Senderens hydrogenated carbon monoxide over nickel to produce methanol [51].

1913: BASF was awarded a patent covering production of hydrocarbons and oxygenates by catalytic hydrogenation of carbon monoxide at high pressure over cobalt catalysts [52].

1923: Franz Fischer and Hans Tropsch reported their work on the hydrogenation of carbon monoxide over alkaline iron catalysts at 10 – 15 MPa and 400 °C [53], calling their mixture of oxygenates and hydrocarbons "synthol".

1923: BASF and I. G. Farben were awarded patents covering zinc-based, iron-free catalysts for the synthesis of methanol.

1926: Fischer and Tropsch were awarded a patent describing the synthesis of hydrocarbons over iron catalysts at 0.1 MPa and 240 – 300 °C [54]; however, activity of these catalysts under these conditions and conversions of synthesis gas to oil was low [16].

1928 – 1930: P. K. Frohlich and W. K. Lewis worked on the synthesis of higher alcohols using alkalized $ZnO - Cr_2O_3$ catalysts [55].

1936: The first four German Fischer – Tropsch (FT) plants were commissioned, having a total capacity of 200 000 t/a of hydrocarbons [56]; the catalyst used was based on cobalt, having the approximate composition by mass Co : ThO_2 : MgO : kieselguhr of 100 : 5 : 8 : 200 [57].

1936 – 1937: Fischer and Helmut Pichler discovered that hydrocarbon synthesis over iron catalysts was greatly improved at a higher operating pressure

(0.5 – 2 MPa), making alkalyzed iron catalysts a possible replacement for the cobalt-based systems; the lifetime of iron catalysts was greatly improved under these conditions [57].

1939 – 1944: The Germans embarked on a research and development program to perfect an iron-based catalyst to replace the cobalt catalysts being used in existing Fischer – Tropsch plants; reactor development was intensified during this period, including fixed-bed reactors with recycle, as well as slurry reactors [55].

1943 – 1944: Herbert Kölbel coordinated a series of tests held at Schwarzheide to screen suitable iron catalysts to replace the cobalt catalysts being used in existing reactors [58]; tests were successful but iron catalysts were not used in the German production plants during World War II [55], [57].

1944: Nine Fischer – Tropsch plants were operated in Germany, producing ca. 700 000 t/a [57]; all plants used the Ruhrchemie synthesis process and the cobalt – thorium – magnesium catalyst [16].

1947 – 1950: Ruhrchemie and Lurgi formed the so-called Arbeitsgemeinschaft (ARGE) to develop a multitubular, fixed-bed Fischer – Tropsch reactor using a precipitated alkaline iron catalyst, which produced high wax yields [57].

1950: Hydrocarbon Research of Trenton, New Jersey developed a fixed, fluidized-bed reactor to produce FT hydrocarbons from reformed natural gas [55]; the plant, known as Carthage Hydrocol, was located in Brownsville, Texas; in 1953 the plant was shut down and dismantled because of the high cost of natural gas [55].

1953: H. Kölbel and P. Ackerman directed the successful operation of a 10 t/d, pilot-scale, slurry-phase Fisher – Tropsch reactor system at Rheinpreussen–Koppers in Germany; this reactor used a precipitated iron FT catalyst suspended in a heavy liquid heat transfer medium through which synthesis gas was bubbled.

1955: The first SASOL plant (SASOL I) was commissioned in South Africa (construction began in 1952); this indirect liquefaction plant used Lurgi dry-ash gasifiers to produce the synthesis gas from coal and two types of F – T synthesis processes: (1) ARGE fixed-bed process, developed by Ruhrchemie and Lurgi, (2) circulating entrained-flow reactor developed in the United States by the M. W. Kellogg Co.; both synthesis reactors used iron catalysts; the fixed-bed FT unit operated as expected, but the entrained system was inoperable commercially until substantial modifications were made by SASOL; extensive entrained-flow catalyst research was necessary before a viable catalyst with acceptable life and selectivity was formulated [57]; not until 1960 did the circulating entrained-flow FT system first achieve steady-state, reliable, continuous operation (system is now known as the SASOL Synthol system).

1966: ICI of the United Kingdom developed a low-pressure process for production of methanol from synthesis gas using a copper – zinc catalyst in a gas-cooled reactor.

1975: SASOL decided to build another much larger plant known as SASOL II, at Secunda, South Africa [59]; the SASOL II plant came on stream in 1980 and produced ca. 8000 m^3/d of liquid fuels; SASOL II used Lurgi dry-ash gasifiers to gasify the coal and Synthol circulating entrained-flow Fischer – Tropsch synthesis units to produce liquid hydrocarbons.

1976: Mobil developed a process for converting methanol to gasoline by using a shape-selective zeolite catalyst known as ZSM – 5; this process was known as the Mobil methanol-to-gasoline (MTG) process.

1979: SASOL decided to build SASOL III, a mirror image of SASOL II, in South Africa because of the continuing deterioration in the crude oil situation [59]; this plant came on stream in 1982.

1981: A plant was initiated in New Zealand to produce methanol from abundant cheap natural gas and to convert this methanol to gasoline by using the MTG process; this plant, designed to produce 2700 m^3/d of gasoline, came on stream in 1985 [21].

1987: The South African Government announced that the Mossgas project would be established for the production of synthetic fuels from two gas fields on the south of Mossel Bay. The offshore platform supplied the first gas in 1992 and the onshore plant including a Synthol reactor started production with full capacity in 1993.

1989: The first commercial SASOL Advanced Synthol (SAS) reactor, a conventional fluidized-bed high-temperature Fischer – Tropsch reactor, was brought into operation at Sasolburg, South Africa. The reactor capacity was about 530 m^3/d. This development was preceded by the operation of a demonstration-scale reactor. Both the demonstration-scale reactor and the commercial reactor were subsequently modified to operate as slurry-phase reactors [60].

1990: SASOL operates a demonstration-scale slurry-phase bubble-column reactor using an iron-based catalyst to convert coal-derived synthesis gas to liquid products. The plant is located in Sasolburg, South Africa.

1992: Slurry-phase Fischer – Tropsch technology was demonstrated at the LaPorte Alternative Fuels Development Unit, Texas, sponsored by the DOE, Air Products, Exxon, Shell Oil, Statoil, and UOP. DOE's advanced catalyst development program includes iron- and cobalt-based catalysts with specific goals for improved catalytic activity, selectivity, attrition resistance, and stability. An efficient catalyst – wax separation system is being devoted to prevent catalyst loss and to guarantee product quality. For oxygenates development, several different technologies are being developed concurrently for the conversion of coal-derived synthesis gas into marketable oxygenate fuels and chemicals, such as alcohols, ethers, and olefins. Air Products successfully developed and demonstrated a one-step process for synthesizing dimethyl ether from coal-derived synthesis gas [10].

1993: A Commercial slurry-phase reactor was commissioned at SASOL I in Sasolburg and the Synthol reactors ceased operate at this site. The slurry-phase reactor uses an iron based catalyst and produces 400 m^3/d of liquid products with the same product spectrum as the ARGE reactors. At the same time an 800 t/d ammonia plant was added to the site as well as expanding the town gas production [61].

1993: The Mossgas plant was commissioned. The plant converts natural gas to liquid fuels using the Synthol technology licensed from SASOL. Total conversion capacity installed amounts to about 4000 m^3/d with three reactors.

1993: Shell starts up a commercial plant using four reactors to convert synthesis gas derived from natural gas to mainly middle distillate products at Bintulu in the State of Sarawak, Malaysia. The plant capacity is about 2000 m^3/d. The plant has operating flexibility to also produce low molecular mass paraffins and waxes in addition to middle distillate fuels and naphtha. The production rate of the former products can be varied to match the smaller market demand [20].

1999: All the circulating fluidized-bed (CFB) Synthol reactors at SASOL II and SASOL III at Secunda, South Africa are replaced with new SASOL Advanced Synthol (SAS) reactors. The 16 CFB reactors each with a capacity of 1200 m^3/d are replaced by 4 SAS reactors each with a capacity of 1700 m^3/d and a further 4 SAS reactors each with a capacity of 3200 m^3/d, giving a total installed capacity of 19 600 m^3/d [62].

1999: SASOL proceeds to basic engineering for a 5000 m^3/d plant to convert natural gas to liquids at Escravos, Nigeria in a joint venture with Chevron. SASOL's Slurry Phase Distillate (SPD) Process licensed to the venture is based on the operation of a supported cobalt catalyst using coal-derived synthesis gas in the demonstration slurry-phase reactor at the Sasolburg site in South Africa. SASOL and Chevron announce a global alliance to use and license the SASOL SPD Process for future gas to liquids (GTL) projects.

1999: A DME pilot plant with a capacity of 5 t/d was commissioned at Taiheiyo Coal

Mining's site in Hokkaido. NKK Corporation started to establish the direct synthesis technology for the low-cost mass production of DME [63].

Although the commercial-scale operation of direct coal liquefaction plants, had been demonstrated in Germany, coal-derived liquids could only be produced at high costs. Incentives for further research were limited until the 1970s, primarily due to the availability of vast reserves of inexpensive oils discovered in the Middle East in the late 1940s. The two oil crises in 1973 and 1978 sky-rocketed the price of crude oil, which jumped to $ 40/bbl at maximum. Since then, developed countries have paid great efforts to reduce the ratio of petroleum in the energy consumption.

Coal is a major oil substitute (see Table 3), its clean use technologies have been pursued and developed. Coal liquefaction is expected to supply liquid fuels for transportation. The price of petroleum is now stable after the success of developed countries to reduce the petroleum ratio, and this leads to sufficient supply of petroleum at present. No necessity of coal liquefaction may be recognized right now. In the longer term, the differences between the rates of consumption and the reserves of the different energy forms will inevitably provide the incentive for more widespread and efficient use of coal. The studies in coal liquefaction (direct and indirect) are being planned and implemented with the potential of being key technology processes developed as one of the modules that will be combined into highly flexible energy complexes "Vision 21" in the United States [64], [65].

A rapid economic growth in East Asia with a large population requiring a huge amount of energy, especially transportation fuels, and limited growth of petroleum supply are anticipated to bring about a significant gap between fuel supply and demand. Coal liquefaction is expected to be developed to supply commercially the liquid fuels for transportation at acceptable cost.

In China or Indonesia, the dominant position of coal in the primary energy production and consumption will not change for a considerably long time period. Direct coal liquefaction is an important way to make up for the oil reserves in those Asian countries which have cheap and abundant coal resources suitable for liquefaction. The current feasibility studies, collaborated with Germany, the United States, and Japan, will provide a reliable basis for the construction of direct coal liquefaction plants in commercial scale in the near future.

2. Indirect Coal Liquefaction

Indirect liquefaction of coal is a stepwise process (see Fig. 1). The coal first reacts with steam and oxygen (gasification) to produce a raw mixture of carbon monoxide and hydrogen known as synthesis gas or *syngas.* The water – gas shift reactor adjusts the ratio of hydrogen to carbon monoxide to the requirements of a particular synthesis by means of a reversible reaction between steam and carbon monoxide:

$$H_2O_{(g)} + CO \rightleftharpoons H_2 + CO_2 \tag{1}$$

After purification, the clean syngas is catalytically converted to a wide range of products, such as hydrocarbons, alcohols, aldehydes, ketones, and acids. Production of predominantly liquid hydrocarbons from syngas is known as the Fischer – Tropsch synthesis, which is a commercial process for converting coal into substitute natural gas (SNG), gasoline, diesel oil, wax, and alcohols. Production of hydrocarbons and alcohols by the Fischer – Tropsch synthesis can be represented as follows:

$$2n\,H_2 + n\,CO \longrightarrow C_nH_{2n} + n\,H_2O \tag{2}$$

$$(2n+1)\,H_2 + n\,CO \longrightarrow C_nH_{2n+2} + n\,H_2O \tag{3}$$

$$2n\,H_2 + n\,CO \longrightarrow C_nH_{2n+1}OH + (n-1)\,H_2O \tag{4}$$

where n is an integer.

Reaction (2) represents formation of olefins, reaction (3) of alkanes, and reaction (4) of alcohols. Hydrocarbon products are in the gasoline boiling range (ca. 50 – 180 °C), but not directly suitable for gasoline use because straight-chain structures predominate, giving an intermediate octane number as low as 55 – 65. The intermediate octane number is defined as the average of the research and motor octane numbers. Extensive further treatment is needed to meet octane requirements for gasoline (ca. 87 – 95). However, the fraction that boils between ca. 180 and

Figure 1. Flow sheet for indirect liquefaction process

320 °C has a high cetane number (65 – 75) and provides valuable diesel fuel with little or no additional refining.

A variant of the Fischer – Tropsch synthesis gives methanol in yields that, unlike the hydrocarbon synthesis, approach 100 %. Methanol can be used as turbine and transportation fuel, although its energy content on a volume basis is only half that of gasoline. It can also be converted almost quantitatively to high-octane gasoline by the Mobil methanol-to-gasoline (MTG) process, which uses the highly selective, synthetic zeolite catalyst ZSM-5.

The primary step in the development of indirect liquefaction is the production of clean synthesis gas; thus, development of coal gasification parallels the success of indirect liquefaction. Synthesis gas for the German Fischer – Tropsch plants during World War II was produced from low-temperature cokes gasified in conventional

water – gas generators [16]; development of coal gasification was also proceeding at that time. In the early 1930s, the fixed-bed coal gasifier was being developed jointly by Lurgi Mineralöltechnik, and Sächsische Werke. In 1936, the first commercial Lurgi plant was built at Hirschfelde in Germany for the production of town gas by lignite gasification [66]. The first commercial Winkler fluidized-bed gasification plant was built in 1926 at Leuna, Germany [67]. By 1949, the first commercial Koppers – Totzek (K – T) entrained gasification plant was in operation at Marzingarbe, France [66].

The most reliable commercial coal gasifier available in 1950 was the fixed-bed, dry-ash Lurgi system, which was chosen for the SASOL I plant in South Africa. With extensive improvements, this system has been used in all subsequent SASOL plants.

Continuing advances in gasification in the United States and elsewhere since the 1950s promise to increase the efficiency of indirect liquefaction. The most noteworthy improvements in coal gasification technology have occurred in entrained-flow systems (Shell and Texaco), the agglomerating-ash fluidized system (Kellogg – Rust – Westinghouse, KRW), and the slagging-ash, fixed-bed system (British Gas Corp., BGC).

Currently, the three SASOL plants operating in South Africa represent the only commercial examples of indirect coal liquefaction by the Fischer – Tropsch synthesis in the world. These plants produce a total of more than 20 000 m^3/d of liquid products (supplying over 30 % of South Africa's liquid transportation fuel needs) by using more than 46×10^6 t/a of low-grade coal. Part of this coal is gasified and another part is used to generate the steam and power for the process. SASOL Synthetic Fuels (SSF) produced about 6.8×10^6 t of products in 1998 with a market value about fivefold that of the coal used. SSF's products comprise liquid fuels (sulfur-free gasoline, diesel, and liquefied petroleum gas), pipeline gas, and various chemical and polymer feedstocks, including alcohols, ketones, organic acids, and other solvents, ammonia, sulfur, ethylene, propene, and α-olefins.

The indirect liquefaction of coal provides high-octane gasoline and high-cetane diesel fuel equal or superior to the conventional products of petroleum refining so that no modifications are required to existing distribution systems or existing engines. Indirect liquefaction also allows coal to be used in an environmentally acceptable manner.

The following steps are required for the indirect liquefaction of coal to transportation fuels:

1) Gasifying coal by using oxygen and steam to produce raw synthesis gas
2) Adjusting hydrogen : carbon monoxide ratio (water – gas shift) for compatibility with the FT catalyst system
3) Purifying the raw synthesis gas and removing catalyst poison and excess carbon dioxide
4) Converting the carbon monoxide and hydrogen to hydrocarbons by FT synthesis
5) Refining the raw FT products to produce marketable liquefied petroleum gases, high-octane gasoline, diesel fuel, solvents, and olefins for petrochemical use.

2.1. Preparation of Synthesis Gas

2.1.1. Coal Gasification

Coal gasification represents a thermal balance between the endothermic reactions of carbon with steam and carbon dioxide and the exothermic reaction of carbon with oxygen. Additional processes occurring in gasifiers include coal devolatilization, the water – gas shift, and methanation [68].

	ΔH, kJ/mol
Gasification	
$C + H_2O \longrightarrow CO + H_2$	135.1
$C + 2\,H_2O \longrightarrow CO_2 + 2\,H_2$	96.2
$C + CO_2 \longrightarrow 2\,CO$	173.2
Combustion	
$C + 1/2\,O_2 \longrightarrow CO$	−110.5
$C + O_2 \longrightarrow CO_2$	−393.7
Devolatilization	
Coal $\longrightarrow$ Char + Volatiles	
Water – Gas Shift	
$CO + H_2O \longrightarrow CO_2 + H_2$	−38.5
Methanation	
$CO + 3\,H_2 \longrightarrow CH_4 + H_2O$	−217.6

Gasification technology has advanced greatly since the World War II German indirect liquefaction plants. These plants produced gas with blue water – gas sets that used alternating cycles of "blows," during which the coke in the generator was heated with air; and "runs" or gas-producing periods, when steam was passed through the bed

to produce carbon monoxide and hydrogen [69]. The net lower heating value (LHV) efficiency of this process was ca. 50 %. The net efficiency (LHV) is defined as the energy content of the produced gas divided by the sum of the energy content of the coke consumed plus the energy used to produce steam.

The commercial SASOL processes in South Africa employ the reliable dry-ash Lurgi fixed-bed gasifiers [70], which use low-grade or high-ash coals and operate at high pressure with low oxygen consumption and high carbon conversion. They do, however, suffer from serious disadvantages, including high steam consumption and the production of methane, tars, oils, and phenols. Furthermore, they cannot handle agglomerating coals or fines, but require a coal feed of uniform size.

The performance of different systems is compared in Table 4 [69–74]. The BGC demonstration gasifier, with a coal throughput of ca. 550 – 730 t/d, is located at Westfield, Scotland [70]. The Westinghouse (KRW) gasifier has been operating on a pilot-plant scale in Waltz Mill, Pennsylvania since 1976 with a capacity of ca. 20 t/d [72], [73]. The Shell (formerly Shell – Koppers) gasifier has been operating since 1979 at Hamburg, Federal Republic of Germany, with a capacity of 140 t/d [74].

The net efficiency of synthesis gas production is important, but it is not the only criterion in gasifier selection. Figure 2 compares the output of four gasifiers in terms of product energy; input coal is the total amount of coal used in the indirect liquefaction plant. Fixed-bed gasifiers burn some of the coal in boilers to provide high-pressure process steam. Dry-ash and slagging Lurgi gasifiers use 18 – 20 wt % of the total coal supply for steam production, i.e., only 80 % can be gasified. Fluidized-bed Westinghouse and entrained-bed Shell gasifiers gasify all the coal. Waste heat boilers use the exit gas for steam production, which is essential for improved process efficiency, because 15 – 20 % of the energy is contained in the sensible heat of the exit gas.

Fixed-bed gasification produces considerable quantities of methane and ethane, which are inert in the Fischer – Tropsch synthesis. If exclusively liquid fuels are required, these gases must be reformed to carbon monoxide and hydrogen and recycled, with considerable loss in efficiency. Only 61 % of the energy content of the methane and ethane appears in the liquid products of reforming and resynthesis [71].

Coal pyrolysis in the upper portion of the fixed bed forms tars, oils, and phenols representing more than 10 % of the energy content of the coal feed. These impurities must be removed before further gas treatment.

The ratio of hydrogen to carbon monoxide in the exit gas is an important consideration in the Fischer – Tropsch synthesis. The conventional FT synthesis used at SASOL requires ratios of 1.7 and 2.5, depending on conditions. More advanced gasification systems have low H_2 : CO ratios (see Table 4) and thus, require adjustment by the water – gas shift.

2.1.2. Water – Gas Shift

Modern catalysts for the water – gas shift are resistant to poisoning by sulfur compounds; this ability to process sulfur containing gases is referred to as sour or raw-gas shift. With the older nickel or iron catalysts poisoning was prevented by preliminary gas purification. Commercially important shift catalysts include [68]:

1) High-temperature shift catalysts (440 – 700 °C), e.g., chromium – iron oxide or zinc – chromium oxide
2) Low-temperature shift catalysts (230 – 350 °C), e.g., copper – chromium oxide
3) Raw gas shift catalysts (at 180 – 550 °C), e.g., cobalt – molybdenum sulfide on aluminum oxide or magnesium oxide

2.1.3. Synthesis Gas Purification

Gasifier exit gas contains impurities that interfere with synthesis. Some impurities can be removed mechanically by water washing or by cyclones. Coal dust, ash, tars, and oils can be removed by cooling and scrubbing. Water washing also removes ammonia and phenols. The remaining impurities include hydrogen sulfide, carbonyl sulfide, carbon dioxide, and small quantities of hydrogen cyanide. The upper limit of sulfur allowable in the Fischer – Tropsch and methanol syntheses is 1 ppm (by vol) [68];

Table 4. Gasification performances

Parameter	Blue water-gas	Dry-ash Lurgi	BGC Lurgi	KRW	Shell
Gasification pressure, MPa	atmospheric	2.4	2.4	2.8	4.5
Exit gas temperature, °C	700	540	450	980	1420

Figure 2. Output of different gasifiers

larger amounts rapidly poison the catalysts. Carbon dioxide is less critical and can, in fact, actually improve catalyst performance in the Fischer – Tropsch synthesis.

Hydrogen sulfide and carbon dioxide are acidic and can be removed by physical or chemical absorption [75], [76]. Physical adsorption, following Henry's law, is favored by low temperature and high pressure.

The removal of acid gas may be nonselective or selective. In the former hydrogen sulfide and carbon dioxide are simultaneously removed in a single stage. If acid gas is removed after shift, the gas stream consists predominantly of carbon dioxide, with a few percent of hydrogen sulfide. Selective gas removal produces one stream containing hydrogen sulfide and the other, carbon dioxide [75]. Sulfur can be recovered from the

selective system by the Claus sulfur-recovery process [76].

The Rectisol process is licensed by Lurgi and employed in the SASOL complexes in South Africa [77], [78]; methanol is the adsorbent at low temperature. The Selexol process, licensed by Allied Chemical, uses poly(ethylene glycol) dimethyl ether [77], [78]. The Lurgi Purisol process uses *N*-methyl-2-pyrrolidine (NMP) [77], [78], and the Fluor solvent process uses propylene carbonate [78].

Chemical absorption systems primarily use amines or carbonates to neutralize acidic gases:

$$2\,RNH_2 + H_2O + CO_2 \longrightarrow (RNH_3)_2 \cdot CO_3$$

$$RNH_2 + H_2S \longrightarrow RNH_3 \cdot HS$$

$$RNH_2 + HCN \longrightarrow RNH_3 \cdot CN$$

Heat reverses these reactions, liberating the gases [67].

Carbonates are neutralized as follows:

$$K_2CO_3 + H_2S \longrightarrow KHCO_3 + KHS$$

Carbonyl sulfide (COS) is hydrolyzed to CO_2 and H_2S [77]; the latter is absorbed by the carbonate solution.

The principal chemical absorption processes are Benfield and Catacarb, both potassium carbonate systems [67], and diisopropanolamine (ADIP) [67], *N*-methyldiethanolamine (MDEA) [67], Sulfiban [67], Fluor Econamine [78], and monoethanolamine (MEA) [78], all amine systems.

After purification and shift of the hydrogen: carbon monoxide ratio, the synthesis gas can be converted to hydrocarbons.

2.2. Fischer – Tropsch Synthesis

The Fischer – Tropsch synthesis is a nonselective process that produces a wide range of compounds containing from 1 to > 100 carbon atoms. Only C_1 compounds can be produced with 100 % selectivity. Selectivity can also be high for high molecular mass wax. However, for intermediate products, only certain maximum values are possible; in general selectivities are interrelated [57], [79]. All postulated mechanisms assume that the synthesis occurs by a stepwise growth of hydrocarbon chains, one carbon being added at a time. A probability mechanism of this chain growth, which limits production of gasoline and diesel fuel hydrocarbons (see Section 2.2.3), can be calculated.

At SASOL I in South Africa, iron-based catalysts promoted with potassium and copper are used. One type of iron catalyst is used for the low-temperature Fischer – Tropsch (LTFT) processes used at SASOL I (i.e., ARGE and slurry phase processes) and another one in the high-temperature Fischer–Tropsch (HTFT) process, i.e., the Synthol Process used at Secunda and Mossel Bay in South Africa. A precipitated iron catalyst is used with the LTFT processes while a fused iron catalyst is used with the HTFT processes. Supported cobalt catalysts can also be considered for LTFT processes.

Fischer – Tropsch processes can be used to produce either a light synthetic crude oil (syncrude) and light olefins or heavy waxy hydrocarbons. The syncrude can be refined to environmentally friendly gasoline and diesel and the heavy hydrocarbons to specialty waxes or, if hydrocracked and/or isomerized, to produce excellent diesel fuel, lube oils, and a naphtha, which is an ideal feedstock for cracking to olefins. To give some idea of the flexibility of the potential product spectrum, the gasoline:diesel ratio may vary from 80 : 20 to 20 : 80. In addition, for a total of 50 % potential olefinic petrochemical feedstock, the light olefins (C_2 to C_4) can amount to 25 % of the products, a further 25 % of the product being in the form of olefins in the carbon number range C_5 to C_{10}. On the other hand, waxes can comprise more than 50 % of the total products.

For production of gasoline and light olefins, the FT process is operated at high temperature (330 – 350 °C), for production of waxes and/or diesel fuel, at low temperatures (220 – 250 °C). Traditionally the high-temperature FT process was performed in Synthol circulating fluidized bed (CFB) reactors and the low-temperature FT process in ARGE tubular fixed-bed (TFB) reactors. In the 1990s, much better reactor systems have been developed for both HTFT and LTFT processes. The conditions of both processes are compared in Table 5.

For HTFT the SASOL Advanced Synthol (SAS) reactor with solid – gas fluidization was developed. The SAS reactor gives very much

the same product spectrum as the CFB reactors, but much more effectively and cheaply.

Table 5. Process conditions for Fischer – Tropsch reactors

Parameter	LTFT	HTFT (SAS)
Temperature, °C	220 – 250	330 – 350
Pressure, MPa	2.5 – 4.5	2.5
$CO + H_2$ conversion, %	60 – 90	85

For LTFT, the SASOL Slurry Phase Distillate (SPD) reactor, of the bubble column type, was developed which is a significant improvement over the TFB reactor used in the ARGE process [61], [80]. In the Slurry Phase reactor products can be made with the same carbon chain length distribution as in the TFB reactor with Schulz – Flory distribution α-values of 0.95 and higher (for a definition of α-values see Section 2.2.1). The SPD reactor has a greater flexibility with respect to product distribution than the TFB reactor.

The heavy hydrocarbons from the SASOL SPD process are hydrogenated and converted to specialty waxes. Alternatively these waxy hydrocarbons can be very easily hydrocracked to excellent diesel fuel with a cetane number > 70 and negligible aromatics and zero sulfur content. At 780 kg/m^3 its density is somewhat lower than that of conventional diesel. If hydroisomerized, the waxy hydrocarbons can be used to produce lube oils.

The primary product spectra of the HTFT process are discussed in more detail in Section 2.2.2. The olefins from SASOL's HTFT plants are recovered commercially and ethylene, propene, 1-hexene, and 1-octene are produced more cheaply than from crude oil. The production of butenes, heptenes, and higher olefins in a HTFT plant is also being considered.

Low-Temperature Fischer – Tropsch Reactors. The two types of LTFT reactors are described below [81].

Tubular Fixed-Bed Reactor. The tubular fixed-bed reactor which has been operated by SASOL (using an iron catalyst) since 1953 and by Shell in Bintulu, Malaysia (using a supported cobalt catalyst) since 1993, makes use of tubes into which the catalyst is paced. Syngas is passed downward through the catalyst bed and is catalytically converted to hydrocarbons. The heat evolved is removed through the tube walls to produce steam on the shell side of the TFB reactor.

Slurry Bed Reactor. The slurry bed reactor which was successfully developed and operated by SASOL commercially since 1993, consists of a vessel containing a slurry of process-derived wax with catalyst dispersed in it. Syngas is bubbled through this slurry bed and is converted to hydrocarbons. The heat generated is passed from the slurry to the cooling coils inside the reactor to generate steam.

The light hydrocarbons, which are in the vapor phase, are removed from the freeboard at the top of the SSPD reactor with the unconverted reactants and are condensed in the downstream condensing train. The heavier liquid hydrocarbons are mixed into the slurry from which they are removed in a proprietary solid separation process developed by SASOL. Excellent results are obtained by this separation step.

The conventional TFB ARGE reactor and the state of the art slurry phase reactor are shown in Figure 3. The maximum capacity for a slurry phase reactor is an order of magnitude higher than that of the TFB reactor. The slurry phase reactor is much simpler in construction than the TFB reactor. The suspended cooling coils and a gas distributor give a much cheaper arrangement than the tube and tube sheet arrangement in the TFB reactor. Because of this, the slurry phase reactor lends itself much better to scale-up. At high gas throughputs, the TFB reactor becomes very complex and mechanically difficult to manufacture and the pressure drops across the tubes become excessive. The pressure drop across the TFB reactor varies from 0.3 – 0.7 MPa, depending on operating pressure, whereas it is typically less than 0.2 MPa across the slurry phase reactor. These differences make it possible to design (at present operating pressures of 2.5 MPa) single slurry phase reactors with capacities of 3000 m^3/d.

The most significant advantage of the slurry phase reactor is that it is well mixed and can be operated isothermally. The absence of axial and radial temperature gradients as in a TFB reactor, allows much higher average operating temperatures in the slurry phase reactor and hence higher reaction rates. Together with the more effective contact between the syngas and the catalyst particles, this leads to higher production rates for the same overall reactor dimensions even though

Figure 3. SASOL reactor system for LTFT

the catalyst inventory in the slurry phase reactor is lower than in the TFB reactor. Because all the catalyst particles are flexibly mixed with the slurry at more optimal process and conditions, the yields per reactor volume are higher and the catalyst consumption per ton of product is only 20 to 30 % of that of the TFB reactor. Because of the isothermal nature of the reactor, the easier control of average catalyst life, and the much smaller pressure drops across the reactor, the control of the reactor is much simpler and operating costs are significantly reduced.

High-Temperature Fluidized Bed Reactors. Also two types of HTFT reactors exist, which are described below.

Circulating Fluidized-Bed Reactor. Three Synthol CFB reactors were used commercially by SASOL from 1955 and another sixteen from the early 1980s on. For this type of reactor, fused iron catalyst is circulated with synthesis gas through a complex reactor – hopper – standpipe system and heat is removed as steam through coils suspended in the reactor section. The reactor system is complex and needs a complex support system to cope with the circulating catalyst loads and temperature differences which makes it expensive. The large tonnages of catalyst circulated cause relatively high pressure drops across the reactor system. These and other disadvantages are eliminated when using a SAS reactor which makes use of conventional solid – gas fluidization.

SAS Reactor. The Synthol CFB and SAS reactors are shown in Figure 4. The SAS reactor is a vessel containing a fluidized bed consisting of fused and reduced iron catalyst. Syngas is bubbled by means of a gas distributor through the bed where it is catalytically converted to hydrocarbons which at the process conditions of about 340 °C and 2.5 MPa, are in the vapor phase. The products and unconverted gases leave the reactor through internal cyclones. The SAS reactor is operated such that the cyclones can retain the catalyst so effectively that, in contrast to the CFB reactors, scrubber towers are not needed to remove the last traces of catalyst before the product stream is passed to the condensing train.

The major advantages of the SAS reactor over the CFB reactor are its simplicity, ease of operation, lower operating cost due to elimination of the catalyst recycle and lower maintenance, and in general higher conversions at higher gas loads. The latter together with the fact that more cooling coils can be installed in the SAS reactor and more heat can be removed, allows for larger capacity equipment which translates into advantages of economy of scale. Maximum capacities

Figure 4. SASOL reactor system for HTFT

of 3200 m^3/d per reactor have been installed at the Secunda site.

2.2.1. Mechanisms

The mechanism of the Fischer–Tropsch synthesis is uncertain, but three theories have been developed [57], [82], [83].

In the first, the carbon monoxide dissociates at the catalyst surface (**M**) to carbon and oxygen atoms. Chemisorbed hydrogen reacts with the carbon to form CH_x entities, which combine into hydrocarbon chains. Chain termination produces α-olefins or alkanes (see reaction scheme 1). To account for the formation of oxygen compounds, a parallel mechanism postulates their production on oxide components of the catalyst surface [83].

In the second theory, carbon monoxide does not dissociate, but is hydrogenated to form oxymethylene species, which condense on the catalyst surface to propagate the hydrocarbon chain (reaction scheme 2).

In the third theory, the CO molecule does not dissociate, but inserts in an **M**–H or an **M**–C bond (reaction scheme 3) [84].

Acids	0.2	0.4	1	NA ∗
Total	100.0	100.0	100.0	100.0

∗ NA = not available.

This mechanism has been widely accepted because CO insertion is known to occur with homogeneous catalysts [57]; however, the evidence is inconclusive for heterogeneous systems. A generalized mechanism that incorporates all three of these schemes has been proposed [59] (see nextpage).

2.2.2. Product Selectivity and Characteristics

The ARGE fixed-bed reactor operates at relatively low temperature and is intended to produce a large quantity of wax and a minimum of methane. The objective of the Synthol reactor, on the other hand, is to maximize production of materials in the boiling range of gasoline. As mentioned previously, formation of waxy material must be avoided or catalyst particles stick together, resulting in bed defluidization. Product selectivities obtained with the SASOL fixed-bed ARGE system and Synthol reactors are shown in Tables 6 and 7. The two sets of data for the ARGE system probably represent different catalyst ages.

Table 8 shows the typical product composition for LTFT and HTFT reactors with iron catalyst [85].

Because of the higher operating temperature, Synthol gasoline contains less paraffinic and more olefinic, aromatic, and oxygenated components than ARGE gasoline. The latter has a high percentage of *n*-alkanes and a low research octane number (RON) of 35, but the diesel has a high cetane number of 75. Synthol gasoline, with its high olefinic and some aromatic content, has a higher RON of 65, but an octane number that is low for gasoline. The Synthol diesel fuel has a cetane number of 55.

Reaction scheme 2

Initiation

Propagation

Termination

denotes a surface bond of indefinite order

Reaction scheme 3

Table 8. Typical product compositions for LTFT and HTFT reactors (with iron catalyst) [85]

	TFB reactor		SSPD reactor		HTFT	
	C_5-C_{12}	$C_{13}-C_{18}$	C_5-C_{12}	$C_{13}-C_{18}$	C_5-C_{10}	$C_{11}-C_{14}$
Paraffins, %	53	65	29	44	13	15
Olefins, %	40	28	64	50	70	60
Aromatics, %	0	0	0	0	5	15
Oxygenates, %	7	7	7	6	12	10
n-Paraffins, %	95	99	96	95	55	60

The C_3 Synthol hydrocarbons are 86 % olefinic, compared to 60 % for those from the ARGE process. For the C_4 hydrocarbons, the corresponding figures are 82 % and 56 %. The high percentage of C_3 and C_4 olefins is a great advantage, because these olefins produce more gasoline by catalytic polymerization and alkylation.

The selectivities obtained in the SAS reactors are very similar to those in the Synthol CFB reactors because both processes use a catalyst with the same composition. A slightly lower methane selectivity can be attained in the SAS reactor because it is operated more isothermally.

The Slurry Phase Distillate process is designed to produce predominantly middle distillate fuels such as gasoline or diesel. At the same time a small amount of naphtha is manufactured as coproduct. These fuels are compatible with existing petroleum derived fuels, and thus no engine modifications or special distribution infrastructure are necessary [86]. At the same time, this synthetic diesel has several environmental advantages over conventional fuels. It has superior combustion characteristics due to its high cetane number (> 70), and is free of sulfur and aromatic compounds (see Table 9).

Environmental concerns have already led to specifications on fuels being tightened in several regions. This is expected to continue, resulting in more stringent specifications in the future. Some refiners may face difficulties in meeting these specifications due to either equipment or feedstock limitations. The environmental advantages of the synthetic product will in this case result in synthetic diesel selling at a premium rate compared with conventional diesel (expected at $ 2.4/bbl premium) for use as a blending component.

Table 9. Comparison of the quality for diesel fractions [86]

	SPD process	Conventional
Sulfur	< 10 ppm	500 ppm
Aromatics	< 1 %	10 – 25 %
Cetane number	> 70	45

The emissions from diesel engines operating on standard, "reformulated", and Fischer – Tropsch diesel fuels have been measured by the South West Research Institute, a large independent fuels and lubricants testing organization in the USA (see Table 10). These tests showed that Fischer – Tropsch diesel results in reduced exhaust emissions (particulates, nitrogen oxides, carbon monoxide, and unburned hydrocarbons) compared to both the standard and the "reformulated"diesels [86].

Table 10. Comparison of Fischer – Tropsch diesel in SWRI diesel engine emission tests [86]

Reduction in	Average diesel	Reformulated diesel
Hydrocarbons	33 %	20 %
CO	46 %	36 %
NO_x	8 %	4 %
Particulates	30 %	26 %

The coproduction of some chemicals is possible with the Slurry Phase Distillate process. The products are primarily a mixture of linear paraffins and olefins, with a wide range of carbon chain lengths. It is feasible to recover linear paraffins that can be used for the manufacture of detergent alkylates and other chemical uses. The separation of linear olefins for the production of detergent feedstock, and the production of lubricating oil base stocks, are also possible. The recovery of these fractions is economically justified for a large scale facility consisting of several modules, as these cuts form only a small fraction of the overall production [86].

2.2.3. Catalytic Selectivity

Fischer – Tropsch processes include catalytic carbon – carbon and carbon – hydrogen bond formation and carbon – oxygen bond rupture [82]. Whatever the mechanisms, the resulting hydrocarbon chain distribution can be explained by a polymerization process, adding one carbon atom at a time to the growing alkyl chain. At any point in the chain, growth can be terminated by hydrogen atom addition or by α-hydrogen abstraction, followed by desorption from the catalyst surface. This process results in a distribution of chain lengths, as in all polymerization processes. Product distribution can be predicted accordingly. The Schulz – Flory distribution can be used to predict selectivity, assuming that all hydrocarbon species on the catalyst surface, regardless of chain length, add a carbon atom with equal probability to produce a chain that is one unit longer [88], [89]. For a hydrocarbon chain having n carbon atoms, the probability of poly-

merization at the first carbon and at each successive carbon is α; the probability that polymerization does not occur at the final carbon atom is $(1-\alpha)$. Thus, the probability that the hydrocarbon chain is composed of n carbon atoms is:

$$P_n = \alpha^{n-1}\,(1-\alpha)$$

Therefore, P_n is equivalent to the mole fraction of the nth oligomer. If the assumption is made that the molecular mass of the monomer is the same, independent of position, the mass fraction (W_n) is simply the mole fraction multiplied by the chain length n and divided by 1 $(1-\alpha)$ (the average degree of polymerization). The equation becomes:

$$W_n = n\alpha^{n-1}\,(1-\alpha)^2$$

Rearranging and taking logarithms gives the Schulz – Flory equation:

$$\log\frac{W_n}{n} = n\log\alpha + \log\frac{(1-\alpha)^2}{\alpha}$$

When $\log\frac{W_n}{n}$ is plotted against n, a straight line of slope $= \log\alpha$ should be obtained if the Schulz – Flory polymerization mechanism is obeyed. With increasing α, the product contains higher molecular mass hydrocarbons. The chain growth probability distribution results in a broad Fischer – Tropsch product spectrum. In addition, only C_1 hydrocarbons can be produced with 100 % selectivity (i.e., when $\alpha = 0$). The Schulz – Flory distribution places a significant limitation on the maximum yield of the transportation fuel fraction. Selectivity as a function of α is shown in Figure 5 [57]. Chain growth is influenced by temperature, pressure, feed composition, and catalyst [55], [90], [91].

Figure 5. Calculated product selectivities from Schulz – Flory analysis

The SASOL operation uses a precipitated iron catalyst in the LTFT reactors (ARGE and Slurry Phase) and a fused iron catalyst in the HTFT Synthol reactors. The fixed-bed catalyst is activated with hydrogen under mild conditions to produce the large metallic surface area necessary for high activity [57]. Selectivity is apparently influenced by the activation or conditioning process. Copper increases the rate of iron oxide reduction and the activity of the catalyst, but not its selectivity for wax [57]. Synthesis gas converts the metallic iron in the partly reduced catalyst to a carbide form (Fe_5C_2) known as Hagg carbide [57]. Promoters, such as K_2O, increase α, i.e., selectivity for longer hydrocarbons, and production of acid. Catalytic activity passes through a maximum with increasing K_2O content. Among support materials for the precipitated iron catalyst, silica gives both the highest activity and the highest wax selectivity [57].

The Synthol catalyst is prepared from mill scale (waste iron) containing small amounts of impurities, such as SiO_2, TiO_2, MgO, and Al_2O_3. The catalyst and promoters are electrically fused into ingots, which are crushed to the necessary particle size and then reduced with hydrogen in fixed fluidized-bed reactors. The surface area increases according to the degree of reduction to a final value between 2 and 30 mg^2/g; pore volume also increases [57], [58]. Potassium is the most important promoter [59]. Structural promoters (Al_2O_3, MgO, and Cr_2O_3) increase and stabilize the surface [57].

Increased temperature in the Fischer – Tropsch synthesis reduces α and favors lower molecular mass products, the chemical characteristics of which also vary (see Tables 11 and 12) [57], [59].

Table 11. Influence of temperature on selectivity of Synthol catalysts [57], [59]

Temperature, °C	Methane selectivity,	Ratio $C_3H_6 : C_3H_8$	Aromatics in gasoline, wt %
310	10	11	4
330	14	10	8
350	17	9	10
360	20	8	13
370	23	6	18
380	28	4	26

Table 12. Influence of temperature on selectivity of ARGE catalysts [57], [59]

Temperature, °C	Wax selectivity, %	Olefins in diesel, wt %
213	47	45
227	34	39
237	24	33
247	17	40

Gas composition and pressure also influence catalyst selectivity [57], [59], probably because, at the catalyst surface, hydrogen favors chain termination and carbon monoxide favors chain propagation. This suggests a correlation between product selectivity and the ratio of hydrogen to carbon monoxide in the feed gas. Wax formation in the fixed-bed reactor is in fact correlated with the H_2 : CO ratio; lower values favor polymerization and higher values favor wax production (higher α). The total reactor pressure, however, has little or no effect on selectivity [59].

This correlation is not observed with the fluidized-bed Synthol catalyst system. At SASOL methane selectivity has been found to correlate with the function:

$$\frac{P_{H_2}^{0.5}}{(P_{CO}+P_{CO_2}+P_{H_2O})}$$

Sulfur poisoning decreases the activity of the Synthol catalyst but increases the formation of olefins and higher hydrocarbons [92]. The structure of the Synthol catalyst, under synthesis conditions, changes continuously from the freshly reduced catalyst to the fully mature catalyst [62]. The main reason for this change is carbon formation during the synthesis process. The change in morphology of the catalyst can affect the catalyst's product selectivity after low-level sulfur poisoning.

2.2.4. Refining of Crude Products

Crude Fischer – Tropsch products from Synthol and ARGE units require extensive refining for use as gasoline and diesel fuel (see Table 13).

Table 13. Refining of Fischer – Tropsch products

Refining process	Purpose
FT product fractionation	separation into light gases and feeds for polymerization and hydrotreating
FT product hydrotreating	saturation of olefins and destruction of alcohols and acids
Hydrotreated product fractionator	separation of hydrotreated products into pentane–hexane stream for isomerization, C_7-C_{11} for reforming, and diesel and fuel oil products
Catalytic reforming	aromatization to increase octane number of gasoline stream
C_5-C_6 Isomerization	isomerization of straight chains to increase octane number of hexanes and pentanes
Catalytic polymerization	polymerization of propene and butene to gasoline
Alkylation	catalytic alkylation of isobutane and unpolymerized C_3-C_4 olefins to increase gasoline yield
Polygas hydrogenation	saturation of olefins in heavy catalytic polygasoline
Alcohol recovery	preparation of marketable alcohol mixture
Wax hydrocracking	cracking of wax components into gasoline and diesel hydrocarbons

Figure 6 illustrates an indirect liquefaction plant producing transportation fuels. If only Synthol reactors are used, as at SASOL II and III, the wax hydrocracker is eliminated. Wax produced in ARGE units can be selectively cracked to $C_1 - C_4$ hydrocarbon gases, gasoline, and diesel in the proportions 5 : 15 : 80 (by mass) [93]. SASOL II and III operations resemble those described in Table 13 [94] (see Section 2.2.6).

2.2.5. Integrated Plant Configurations

The flow sheet of an integrated indirect coal conversion plant, combining the steps discussed in previous sections, is shown in Figure 7. In the upper configuration, designated as the *mixed-output mode,* liquid transportation fuels and substitute natural gas (SNG) are produced. In the lower configuration, the *all-liquid-output mode,* the light hydrocarbon gases are autothermally reformed back to synthesis gas; the net output contains only C_3 and higher liquid hydrocarbons. The SASOL II and III operations are of this

Figure 6. Flow sheet for Fischer – Tropsch products

Figure 7. Flow sheet for integrated liquefaction

type. The flow sheet was adapted from studies conducted by Mobil Research and Development Corp. [71] and Mitre Corp. [70].

The plant represented in Figure 7 is designed to process 25 200 t/d of Wyoming subbituminous, noncaking reactive coal. To meet plant requirements, ca. 18 % of the coal is needed to produce high-quality steam, most of which is used for oxygen production for the gasification section. Fixed-bed, dry-bottom Lurgi gasifiers produce the synthesis gas, which is very wet, with a molar hydrogen : carbon monoxide ratio of ca. 2 : 1. After being quenched with water to remove tars and particulates, the synthesis gas is split into two streams. About 20 % is passed to shift reactors, where the hydrogen : carbon monoxide ratio is raised to 10 : 1. Recombination of the two streams gives an overall H_2 : CO ratio of 2.5 : 1, as required for Synthol reactors. The combined gas is purified by the Lurgi Rectisol process, passed to the Synthol units, and refined (see Section 2.2.4).

Table 14. Calculated yields from model liquefaction plants

Products	Mixed output	All-liquid output
SNG, m^3/d (STP)	4.91×10^6	–
Gasoline, m^3/d	2160	4465
Propane, m^3/d	176	387
Butane, m^3/d	23	51
Diesel, m^3/d	324	807
Fuel oil, m^3/d	99	217
Alcohols, m^3/d	291	640
Annual thermal output (LHV ∗), GJ/a	85 627 000	65 418 000
Liquid yield, m^3 C_4^+/t dry coal	0.159	0.334
Overall efficiency (LHV ∗), %	54	41
Total plant coal (LHV ∗), GJ/a	158 424 000	158 424 000

∗ LHV = lower heating value.

Figure 8. Flow sheet for SASOL I synthesis

The gasification process includes auxiliary units for gas – liquid separation and recovery of phenol, sulfur, and ammonia. These units contribute to pollution control (see Section 2.5).

Off-site units are required for oxygen production, steam boilers and superheaters, stack gas precipitation and flue gas desulfurization, coal handling and preparation, ash removal, water supply for boilers and cooling towers, power generation, wastewater treatment, storage, fuel blending, and catalyst preparation.

The calculated yields based on a model commercial plant for mixed-output and all-liquid operation are given in Table 14. In the mixed-output mode, 65 % of the thermal output is in the form of SNG, which originates from the Lurgi gasifier and also from the Synthol reactor. In the all-liquid mode, the methane and ethane are reformed and resynthesized to liquids, reducing overall plant efficiency from 54 to 41 %. Overall plant efficiency is defined as the LHV energy content of all the products divided by the LHV energy content of the total feed coal.

Energy relations in the all-liquid mode as a percent of total plant coal input energy (LHV) are as follows:

Input coal	100 %
Gasifier output	74 %
Synthesis gas	63 %
Clean gas	62 %
Raw products	45 %
Refined products	41 %

The raw gasifier output represents ca. 74 % of the energy of the total feed coal and includes the tars, oils, and phenols recovered from the wash and wastewaters. A calculation based only on gases produced would reduce the efficiency to ca. 65 %. After the shift and cleaning steps, the energy remaining in the gas represents 62 % of the total input coal. In the all-liquid mode, the methane and ethane are reformed to synthesis gas with a loss of energy; thus, the crude products represent only ca. 45 % of the input coal energy. Refining to final products lowers this value to 41 %.

2.2.6. Commercial Practice at SASOL

The SASOL plants, in operation in South Africa since 1956, are the only indirect coal liquefaction plants in the world that currently produce liquid transportation fuels by the Fischer – Tropsch synthesis. The original Sasol-

burg site has been converted entirely to produce products other than liquid transportation fuels, mainly waxes, paraffins, ammonia, and town gas (see Fig. 8).

The Secunda site consists of two identical plants previously called SASOL II and SASOL III but now referred to as SASOL West and SASOL East. These plants are virtually identical and they now also produce a wide range of petrochemical products and a methane-rich pipeline gas.

There are 36 gasifiers at each plant (72 in total at Secunda). The Mark-IV Lurgi dry-ash gasifiers used have 3.85 m internal diameter. They were originally designed to produce ca. 55 000 m^3/h (STP) of dry raw gas [59], but are now capable of producing about 85 000 m^3/h. The raw gas from these gasifiers is cooled in waste-heat boilers and washed with water. Particulates, ammonia, tars, oils, and phenols are removed. The cooled, stripped gas, still containing hydrogen sulfide and carbon dioxide, is purified by a chilled methanol wash in Rectisol units, leaving less than 40 ppb (by volume) of H_2S and less than 1 % CO_2.

The product work-up system used for the Secunda plants is shown in Figure 9. The tail gas from the separator is scrubbed to remove carbon dioxide and then fractionated in a cryogenic unit. The recovered ethylene from this cryogenic unit is a valuable chemical feedstock [59]. Some pipeline or town gas is withdrawn from the methane-rich product stream from the cryogenic unit and the remainder is autothermally reformed to synthesis gas and recycled. The propene was originally polymerized to either gasoline or diesel in a catalytic unit that can also accept butene as a feedstock if higher diesel yields are desired. Nowadays the propene is mostly recovered as a valuable petrochemical feedstock and the butene is processed to gasoline in an alkylation unit.

As shown in Figure 9, pentane and hexane are isomerized and the $C_7 - C_{11}$ hydrocarbons are reformed over a platinum catalyst to increase the octane rating of the gasoline. Higher carbon number fractions are catalytically hydrodewaxed and marketed as a zero sulfur diesel fuel [94]. Increasingly α-olefins such as 1-hexene and 1-octene are being recovered as petrochemical feedstocks.

2.2.7. New and Developing Technologies

The conventional fluidized-bed reactor concept has been developed and scaled-up by SASOL to the limits of this technology at the Secunda site in South Africa. This type of reactor was first operated at the Hydrocol plant in Brownsville, Texas in the early 1950s. The tubular fixed-bed reactor concept used in Germany in the early applications (maximum production in 1944) has now been developed further and scaled up by Shell to the limits of this technology for the commercial plant in Bintulu, Malaysia.

The slurry phase or slurry bubble column reactor (the successor to the TFB reactor for LTFT) is potentially the best reactor choice for the Fischer – Tropsch synthesis and it has yet to be developed to its full potential in a commercial application. This type of reactor was first applied in a demonstration unit at Rheinpreussen, Germany, in the 1950s using an iron-based catalyst for the production of gasoline. SASOL, Statoil, Exxon, Shell, and, more recently, IFP/AGIP have been working on the concept of using a supported cobalt catalyst with this type of reactor. SASOL and Exxon have operated demonstration-scale reactors, and Shell and Air Products have participated in demonstration scale tests using the US DOE facilities at La Porte, Texas. The concept is to produce wax as the main primary product from the reactor which also produces straight-run diesel and naphtha and optionally kerosene and liquefied petroleum gas (LPG). Only SASOL has operated a commercial-scale slurry phase reactor. The characteristics of the Rheinpreussen plant were as follows [95]:

Reactor dimensions	155 cm diameter 8.6 m height
Slurry volume	10 000 L
Catalyst, Fe	800 kg
Production output	11.5 t/d
Average temperature	268 °C
Pressure	1.2 MPa
Feed gas rate at STP	2700 m^3/h
Hourly space velocity of gas	270 L of gas per liter of expanded slurry
Carbon monoxide conversion	91 mol %
Overall syngas conversion	89 mol %
Syngas feed ratio H_2 : CO	0.67
Linear velocity of syngas	9.5 cm/s
Catalyst composition:	
Fe	1000 g/kg
Cu	1 g/kg
K_2O	0.5 – 5 g/kg

Figure 9. Flow sheet for SASOL II products workup

The height of the expanded liquid-catalyst bed was kept constant by adding melted wax or by withdrawing the products with a high boiling point through a pressure filter to remove the catalyst. The product distribution (in wt %) obtained from the operating plant at maximum gasoline production was as follows:

Methane and ethane	3.2
Ethylene	3.6
Propene	18.0
Propane	4.5
Butene	3.8
Butane	1.3
Boiling range	
40 – 180 °C	53.6
180 – 220 °C	4.0
220 – 320 °C	6.0
>320 °C	1.9

High selectivity for gasoline was achieved, almost 54 % compared to the 48 % predicted from probability considerations. If propene and butene polymerization was included, gasoline production reached 73 % compared to 62 % for Synthol gasoline. Attempts to repeat these results have been unsuccessful [97–100].

In a later investigation at Mobil, slurry-phase Fischer – Tropsch synthesis was combined with fixed-bed zeolite processing of the crude products [101]. Processing of such products over zeolite ZSM-5 was known to form high-octane gasoline by a combination of isomerization, aromatization, alkylation, and elimination of oxygen compounds [102].

In the first stage of the *Mobil two-stage process,* the Fischer – Tropsch synthesis was carried out in a slurry reactor containing alkaline-promoted iron catalysts in a liquid heat transfer medium. Product selectivities were as follows [101–103]:

Reactor conditions	
Pressure	1.48 MPa
Temperature	260 °C
H_2 : CO Molar ratio	0.68
Hourly space velocity at STP, L/g Fe catalyst	2.6
Conversion data, mol %	
Hydrogen	79
Carbon monoxide	92
Syngas	87
Selectivities, wt %	
CH_4	6.8
C_2H_4	1.6
C_2H_6	2.8
C_3H_6	7.5
C_3H_8	1.8
C_4H_8	6.2
C_4H_{10}	1.8
C_5–C_{11}	18.6
Light hydrocarbons	14.3
Heavy hydrocarbons	27.6
Wax	10.0

When the reactor was operated at low C_1 and C_2 yields (ca. 5 wt %), large quantities of wax (C_{23}+) were produced; this wax was removed to prevent excess liquid buildup, the catalyst was returned to the reactor without deactivation, which may be difficult in a commercial operation. The effect of the zeolite second stage is shown in Table 15.

Table 15. Selectivities before and after ZSM-5 reactor

Products	First stage, wt %	Second stage, wt %
C_1	6.5	6.8
C_2*/C_2**	1.7/2.7	1.0/2.9
C_3*/C_3**	7.1/1.9	2.0/5.6
C_4	5.9	4.7
Iso-C_4 /*n*-C_4	0/1.8	6.6/6.1
C_5–C_{11}	27.1	51.5
C_{12+} (liquid)	33.3	0.8
Reactor wax	12	12
C_5–C_{11}, wt %		
Alkanes	–	49.4
Olefins	–	22.8
Naphthenes	–	4.5
Aromatics	–	23.3

* Saturated.
** Unsaturated.

Research on the Fischer–Tropsch process is continuing at SASOL and elsewhere. Much of this work is aimed at improving selectivity by developing novel catalysts and reactors. SASOL has developed high-activity, long-life, supported cobalt catalysts, that have a longer service life and higher activity than the conventional iron-based catalysts [85]. This more than compensates for the higher raw material costs. However, further work on improving the life of the iron-based catalyst in slurry phase reactors may still result in the use of iron catalyst with low H_2 : CO ratio syngas derived from coal. The iron catalyst exhibits water–gas shift activity which is absent from cobalt-based catalysts. Water–gas shift activity is desirable for low H_2 : CO ratio coal-derived syngas but not for the higher H_2 : CO ratio natural gas-derived syngas.

The selective hydrocracking of Fischer–Tropsch waxes yields 80 % diesel fuel (cetane number ca 70), 17 % naphtha, and 3 % C_1–C_4 hydrocarbon gases. The wax is an ideal hydrocracker feedstock because it contains no aromatic, nitrogen, or sulfur compounds. When combined with the straight-run products (which are typically hydrotreated to remove olefins and oxygenates) the final diesel : naphtha ratio is typically 75 : 25. There is considerable flexibility for the processing of the wax. It may be fed to a Fluidized Catalytic Cracking (FCC) unit to produce gasoline; it may be fractionated and hydroisomerized to produce lubricant base oils, or intermediate severity hydrocracking/hydroisomerization may produce a combination of FCC feedstock, lubricants, diesel fuel, and naphtha. A kerosene or jet fuel product intermediate between diesel and naphtha may also be produced. The naphtha is an ideal feedstock for cracking to olefins since it is completely paraffinic [96].

2.2.8. Advanced Systems

Integrated indirect liquefaction by SASOL technology with two modes of operation was discussed in Section 2.2.5. In the mixed-output mode, gas and liquid fuels are produced together. In the all-liquid-output mode, the C_1 and C_2 hydrocarbons are reformed to synthesis gas and only liquid fuels are produced. The expected effect of using advanced entrained gasification, such as the Shell system, in place of the dry-ash Lurgi is significant, with an increase in net efficiency of ca. 23 % [104]. This would result in a 23 % reduction in gasoline cost if commercial operation matches pilot-plant results.

Predicting the effect of the slurry-phase system and the Mobil two-stage slurry ZSM-5 system is more difficult. However, if the Rheinpreussen-Koppers pilot plant results could

be scaled up, the plant efficiency of a Shell gasification system would increase by an estimated additional 10 % [104].

2.3. Methanol and Methanol to Gasoline (MTG)

Methanol formation can be seen as a variant of the Fischer – Tropsch synthesis:

$$CO + 2\,H_2 \longrightarrow CH_3OH \quad \Delta H_{298} = -90.84\,\text{kJ/mol}$$

$$CO_2 + 3\,H_2 \longrightarrow CH_3OH + H_2O \quad \Delta H_{298} = -49.57\,\text{kJ/mol}$$

Both reactions are exothermic and proceed with volume contraction; they are consequently favored by a low temperature and high pressure.

Both high- and low-pressure processes are available to hydrogenate carbon monoxide. The *high-pressure method* was commercialized by BASF in 1923 [105] and dominated the market in various versions until 1966 [106]. These processes used a zinc – chromium oxide catalyst at or above 340 °C and required a pressure of 30 – 50 MPa to obtain methanol concentrations of ca. 5 – 6 vol % in the effluent gases from the reactor, together with significant amounts of methane, dimethyl ether, ethanol, and higher alcohols.

In 1966 ICI introduced a *low-pressure methanol synthesis* that used a copper – zinc – chromium catalyst at 5 MPa [105]. Other low-pressure processes were developed later by Lurgi Kohle & Mineralöltechnik [107], Mitsubishi Gas & Chemical Co., and Haldor Topsøe [108]. These processes differ primarily in operating pressure, catalyst, and reactor design, especially with respect to heat recovery and temperature control. The ICI and Lurgi processes are dominant.

In the *ICI methanol process,* sulfur-free synthesis gas is mixed with part of the recycle gas, heated, and fed to the converter at 5 – 10 MPa. The remainder of the recycle is used as quench gas and is admitted to the catalyst bed through a series of lozenge-shaped distributors. In the reactor, the CO, CO_2, and H_2 are partially converted to methanol. The hot exit gases are cooled to condense the methanol. Part of the unreacted gases is purged to prevent inert impurities from accumulating; the remainder is compressed and recycled to the reactor. The typical recycle ratio ranges from 5 at 10 MPa to 8 at 5 MPa [108]. Conversion of CO to methanol per pass is normally 16 – 20 %. Feed-gas composition is typically 59 vol % H_2 and 27 vol % CO, to give an H_2 : CO ratio of 2.17.

The ICI process uses a hot-wall, catalytic, fixed-bed, vapor phase, adiabatic reactor designed for rapid catalyst loading and unloading and for efficient mixing of cold and hot gases. The reactor holds a bed of catalyst with quench gas distributors at several levels to control temperature. The bottom catalyst layer is usually kept at ca. 230 °C. Catalyst lifetime is typically 2 – 3 years.

The *Lurgi process* uses a tubular reactor with copper – zinc catalyst packed in vertical tubes that are contained within a reactor shell filled with boiling water. This closely resembles the ARGE Fischer – Tropsch reactor; it differs from the ICI methanol system in having only one feed location. Hot synthesis gas is fed to the top of the reactor and distributed uniformly through the tubes. The heat of reaction is removed by the circulating boiling water [107].

The U.S. Department of Energy (DOE) and the Electrical Power Research Institute (EPRI) have supported research on methanol synthesis by a novel system known as *liquid-phase methanol* (LPM), in which synthesis gas reacts with a catalyst suspended in a liquid heat transfer medium. This reactor resembles a slurry reactor (Section 2.2.7) except for the circulation through an external heat-transfer loop attached to the reactor. The experimental LPM reactor at LaPorte, Texas, is 57 cm in diameter and 5.5 m high [109].

Mobil methanol-to-gasoline process. Methanol can be used as a fuel alone or blended with gasoline. In addition, it can be converted to gasoline by the Mobil MTG process [110]. Methanol as the first stage in the indirect liquefaction affords 100 % selectivity for gasoline, much higher than that obtainable in the Fischer–Tropsch synthesis with its wide range of hydrocarbon products.

In the Mobil MTG process, methanol is dehydrated over the zeolite ZSM-5 catalyst [111], first to dimethyl ether and then to hydrocarbons that are predominantly in the gasoline boiling range, with some LPG and fuel gas [68]. The reaction exotherm ranges from 1.5 to 1.75 kJ/g

methanol, depending on the product distribution [68]. The complex reaction sequence can be represented as follows [68]:

$$2\,CH_3OH \longrightarrow (CH_3)_2O + H_2O$$

$$(CH_3)_2O \longrightarrow (CH_2)_2 + H_2O$$

Light olefins $\longrightarrow$ Heavier olefins

Heavy olefins $\longrightarrow$ Aromatics, alkanes, cycloalkanes

For 100 g of methanol consumed, the stoichiometric yields are 43.75 g of hydrocarbons and 56.25 g of water.

Mobil has developed two reactor configurations: the adiabatic fixed-bed and the fluidized-bed processes. In the *adiabatic fixed-bed process*, two reactors are used in series, the first for dehydrating methanol to an equilibrium mixture of dimethyl ether and water. This mixture is combined with recycle gas from the second reactor and converted to hydrocarbons and water over the zeolite catalyst. The recycle gas, which consists of light hydrocarbons, aids in heat removal from the second stage [68]. The catalyst in the MTG reactor requires regeneration about every 20 d.

Much of the development work has been performed in a 0.64 m^3/d pilot plant at Mobil's New Jersey facility. The dehydration reactor is 5 cm in diameter by 4 m and the conversion reactor is 10 cm in diameter by 4 m. In 1980, the government of New Zealand decided to use this technology in a 2700 m^3/d plant for converting natural gas to gasoline [112].

Development of the *fluidized-bed MTG process* was partially supported by the U.S. DOE. A 0.64 m^3/d pilot plant was operated successfully, demonstrating the following advantages over the fixed-bed process [110]: heat removal at high temperature and mixing of catalyst and reactants are highly efficient, high catalyst activity is maintained with continuous regeneration, and the heat of reaction is utilized to vaporize feed methanol.

Table 16. MTG operations [68], [110]

	Fixed-bed	Fluidized-bed	
	0.64 m^3/d	0.64 m^3/d	16 m^3/d
MTG inlet temp., °C	360	413	407
outlet temp., °C	412	413	407
Gas recycle ratio (molar)	9	0	0
Weight hourly space velocity, (pure methanol)	1.6	1.0	1.1

[a] Based on methanol feed.
[b] NA = not available.
[c] Includes alkylate.
[d] Unleaded product.

The 0.64 m^3/d pilot plant's reactor is 10 cm in diameter and 7.6 m high, with provision for external catalyst circulation and regeneration [113]. In 1980, an international project was initiated to construct and operate the fluidized-bed MTG process on a 16 m^3/d demonstration scale at Wesseling, Federal Republic of Germany. Participants included Mobil, Uhde, and Union Rheinische Braunkohlen Kraftstoff (URBK). Financial assistance was also provided by the U.S. DOE and the Ministry for Research and Technology (BMFT) of the Federal Republic of Germany [110]. The conversion rate has averaged 850 kg/h of methanol, and the plant has met design specifications and target quantities [110]. Conditions and yields are shown in Table 16 for fixed-bed and fluidized-bed operations. The product has the properties of premium unleaded gasoline [68]. The content of durene (1,2,4,5-tetramethylbenzene), which can crystallize in the engine, is kept below 5 wt % by regulating reactor conditions.

2.4. Dimethyl Ether (DME) (see also → Dimethyl Ether)

Dimethyl ether is a new promising substitute fuel for gas turbines, for LPG, and perhaps more importantly, as an alternative diesel fuel. DME has found use as a substitute propellant for the ozone depleting chlorofluorocarbons presently being phased out. The world production (1999) is around 150 000 t/a. The manufacturing process today is based on simple dehydration of methanol. The relatively small quantities of DME produced do not justify investment in new more expensive and sophisticated production facilities yielding higher volumes and lower unit prices. However, recent studies have shown that DME has the potential of being a new significant energy carrier in the future global energy market similar to liquefied natural gas.

DME can be manufactured from nearly all carbon-bearing substances at a price not much above that of standard diesel [114], [115]. DME production from natural gas is outlined in [116–118]. A brief discussion of the production process from coal derived synthesis gas follows. Coal gasification generates a fairly impure synthesis gas, which has to be cleaned thoroughly. The purification of such gas may be done by hot gas cleaning at around 400 °C in order to conserve energy. The conversion of synthesis gas directly through methanol into DME takes place in a synthesis loop consisting of three catalytic fixed-bed adiabatic reactors with indirect cooling. The catalyst applied is a proprietary dual-function catalyst, catalyzing both steps (i.e., methanol and DME synthesis) in the sequential reaction. Significant advantages arise by permitting the methanol synthesis, the water–gas shift, and the DME synthesis reaction to take place simultaneously. The synthesis of DME from synthesis gas involves three reactions:

$$CO_2 + 3\,H_2 \rightarrow CH_3OH + H_2O \quad \Delta H = -50.1\ \text{k/mol} \qquad (5)$$

$$H_2O + CO \rightarrow H_2 + CO_2 \quad \Delta H = -40.9\ \text{k/mol} \qquad (6)$$

$$2\,CH_3OH \rightarrow CH_3OCH_3 + H_2O \quad \Delta H = -23.4\ \text{k/mol} \qquad (7)$$

Reactions (5) and (6) represent a conventional methanol synthesis. This methanol synthesis is restricted by equilibrium, which requires high pressure in order to reach an acceptable conversion. The introduction of Reaction (7), the DME synthesis, serves to relieve the equilibrium constraints inherent to the methanol synthesis by transforming the methanol into DME. Moreover, the water formed in Reaction (7) is to some extent driving Reaction (6) to produce more hydrogen, which in turn will drive Reaction (5) to produce more methanol. Thus, the combination of these reactions results in a strong synergetic effect, which dramatically increases the synthesis gas conversion potential.

Figure 10. Conversion of $C + CO_2$ at equilibrium as a function of synthesis pressure for a typical synthesis gas composition

Figure 10 shows the conversion of $CO + CO_2$ at equilibrium as a function of synthesis pressure for a typical synthesis gas composition. The efficiency of the process and the dual-function catalyst have been demonstrated in a 50 kg/d process demonstration pilot in Haldor Topsøe's facilities in Copenhagen, Denmark. The original catalyst charge has been in operation for more than 15 000 h and demonstrated an excellent stability with an aging profile slower that the of commercial methanol synthesis catalysts.

Subsequently to the start up of the Topsøe pilot plant, Air Products of USA and NKK of Japan have piloted the synthesis of DME from synthesis gas based on slurry bed reactors [119].

NKK began working to develop the direct synthesis technology for DME in 1989 and has established a 50 kg/d bench plant. In 1997, NKK started an R&D project on direct synthesis technology for the low cost mass production of DME using a 5 t/d pilot plant to evaluate the whole system. The basic features of the NKK process are its slurry bed and its newly developed catalyst system which realize the direct reaction (Eq. 8)

of synthesis gas with a H_2 : CO ratio of 1 in the slurry phase. NKK uses a slurry bubble column reactor with an inner diameter of 90 mm and a height of 2 m. The hybrid catalyst containing $CuO-ZnO/Al_2O_3$ and copper-modified γ-alumina showed a high activity for the synthesis of DME in the slurry phase. Optimum synthesis gas conversion (56 %) and high selectivity to DME (98 %) were achieved at the initial H_2 : CO ratio of 1 [120–123]:

$$3\,CO + 3\,H_2 \rightarrow CH_3OCH_3 + CO_2 \qquad \Delta H = -246.1\ \text{kJ/mol} \tag{8}$$

Coal-derived synthesis gas obtained by high-temperature gasification has a H_2 : CO ratio of 0.5 to 1, which has to be adjusted to $H_2 : CO = 2$ by an expensive shift converter before the DME synthesis in order to synthesize DME according to Equation (7). The reaction according to Equation (8) has a substantial advantage regarding synthesis gas preparation and DME conversion [124].

With funds provided by the Agency of Natural Resources and Energy of the Ministry of International Trade and Industry, the Center for Coal Utilization of Japan, Japan is conducting a five year project to evaluate the whole system of the direct synthesis of DME. The project started in the fiscal year 1997 with the cooperation of NKK, Taiheiyo Coal Mining Co., Ltd. and Sumitomo Metal Industries, LTD. In 1999, a 5 t/d pilot plant was constructed at Taiheiyo Coal Mining's site in Kushiro, Hokkaido and the operation was started. The dimensions of the slurry phase reactor are 55 cm inner diameter and 15 m height. The aimed single-pass synthetic gas conversion is around 50 % [124].

2.5. Environmental Protection

Liquefaction plants, like SASOL in South Africa, produce gaseous, liquid, and solid effluents. Emissions into the environment are controlled by integral plant design technologies, some of which are used in related industries, such as utilities or petroleum refining.

Atmospheric pollutants arise from (1) burning coal and fuel gases (2) gasification, (3) coal handling and preparation, and (4) fuel refining. *Combustion-generated pollutants* from the steam and utilities plant are primarily particulates, sulfur dioxide, nitrogen oxides, and volatile organic compounds. Other inorganic pollutants are found in coal, including fluoride, beryllium, lead, and mercury. The known technology for controlling pollution created by coal combustion is, of course, applicable here. Flue gas desulfurization (FGD) units [125], electrostatic precipitators (ESP), and bag houses [126] can be used to control sulfur dioxide and particulates. Nitrogen oxides (NO_x) emissions can be minimized by combustion techniques or chemically [127], for example with Thermal DeNox. The ash and sulfur contents depend on the characteristics of the coal. In the United States, regulations currently exist for coal-fired utilities but not as yet for coal conversion plants; these regulations will most likely be extended as needed [128]. With appropriate design, indirect liquefaction plants can eliminate coal combustion for steam and utilities production. If gasifiers process feed coal, including fines, all the steam and power requirements could be met by combustion in gas turbines of a portion of the cleaned synthesis gas.

The crude gasification product contains almost 100 % of the coal sulfur, mostly as hydrogen sulfide. The sulfur content must be reduced to ca. 1 mg/kg so as not to poison the catalyst. Various processes convert the hydrogen sulfide to elemental sulfur, which is marketable. The most common of these are the Stretford, used at SASOL, and the Claus process, used at several petroleum refineries. The Stretford process was developed by BGC and is used worldwide in over 50 plants [77], [78].

The Claus process has been well established in the refinery and natural gas industries for many years. Several hundred plants operate worldwide, with an average capacity of 100 t/d of sulfur. The correct stoichiometric portion of feed H_2S is oxidized by combustion in a front-end furnace to yield SO_2, which oxidizes the remaining H_2S in downstream catalytic reactors:

$$2\,H_2S + 3\,O_2 \longrightarrow 2\,H_2O + 2\,SO_2$$

$$2\,H_2S + SO_2 \longrightarrow 2\,H_2O + 3\,S$$

Residual sulfur compounds can be removed by the Shell Claus Offgas Treating (SCOT) process

developed in 1972 [129]. The combined gas purification and recovery processes convert 99 % of the sulfur in gaseous compounds to elemental form.

Particulates from *coal handling* and preparation can be controlled by enclosures, sprays, and bag houses. Gaseous pollutants from refining operations and vapor leakages can be controlled by recovery systems and proper maintenance. In general, indirect coal conversion plants do not create major problems of atmospheric pollution; any gaseous effluents can be controlled by known methods [128].

Aqueous effluents or wastewaters arise principally from steam plant blowdowns, gasification wash waters, and Fischer – Tropsch wastewaters. *Steam plant blowdown* creates wastewater identical to that produced by conventional coal-fired utility plants and are not discussed here.

Gasification wash water from Lurgi dry-ash gasification, also called process gas liquor, is treated as follows in the SASOL II and III plants [128]. All the liquor produced by washing and cooling of the exit gases is combined in large separation vessels. This wastewater contains dissolved acid gas, organic acids, tar components, phenols, and ammonia [128]. The last two are removed before attempting to remove the others because they are dangerous to activated sludge microbes employed in water biotreatment. The Lurgi Phenosolvan process, which is also used at the Great Plains gasification plant in North Dakota, removes phenols by solvent extraction [130], [131]. Ammonia is removed by the Chemie Linz Lurgi ammonia process [71], and the wastewater is then treated biologically by activated sludge [128], [132], which, however, does not remove all chemical oxygen demand (COD). Residual COD is attributed to humic acid components, which are apparently harmless [128], but the remaining 1 mg/kg of phenol must be removed by adsorption on granular activated carbon (GAC). The effluent water, which is then colorless and odorless, can be discharged or used as cooling tower makeup water. At SASOL II and III, it is reused for cooling without fouling or corrosion problems [128].

Process wastewater from the Fischer – Tropsch synthesis, after recovery of alcohols and other oxygen compounds, is also given activated-sludge biotreatment.

Solid wastes arise from gasification residue (i.e., ash, slag, and char); wastes generated by grinding and grading the coal; steam plant wastes, such as fly and bottom ash and flue-gas desulfurization residue; water treatment wastes, such as biosludge and salts from blowdowns; and spent catalysts.

The quantity and character of these solid wastes depend, largely, on the gasification process used and the characteristics of the feed coal. The residue from the dry-ash Lurgi gasification process contains some ungasified carbon. The coal used at SASOL II and III produces ca. 12 000 t/d of ash, with a density of ca. 1440 kg/m^3. Fly ash, bottom ash, slag wastes, and FGD wastes from coal combustion have been classified as nonhazardous by the Resource Conservation and Recovery Act (RCRA) of 1976, the major regulation in the United States governing the management of solid wastes [133].

A later regulation temporarily excludes coal gasification wastes from being classified as hazardous [134]. These regulations allow solid wastes from gasification and boiler plants to be disposed of in nonhazardous landfills or settling lagoons. None of the ashes or slags from coal gasification that have been tested by the EPA-approved extraction procedure have been found hazardous [128]. Wastewater treatment sludge is usually incinerated and activated carbon regenerated. Concentrated inorganic salts from cooling tower blowdowns are hazardous and require disposal in lined landfills.

The prior description applies to Lurgi dry-ash gasification combined with the Synthol Fischer – Tropsch synthesis. The *fixed-bed Lurgi gasification system* produces tars, oils, phenols, and such quantities of wastewater as to represent a worst-case environmental scenario. Pollution control is greatly simplified by the use of advanced entrained gasification. The Shell system, for example, produces only carbon monoxide and hydrogen without tars, oils, or phenols, transforms the mineral matter in the coal to a glassy, nonleachable slag, and consumes minimal steam.

Pollution control for indirect coal liquefaction represents 10 – 15 % of the total plant cost

[128]. The degree of protection to be attained depends primarily on cost considerations rather than technical limitations [128].

2.6. Economic Aspects

SASOL, in their 1999 interim report, set an operating cost target for their high temperature Fischer – Tropsch operations at Secunda, excluding capital charges, of $ 11 per barrel. This corresponds to a product cost of just over $ 16 per barrel when allowing for the 90 % yield of a typical modern refinery and a $ 4 per barrel mark-up for the refinery processing. When compared to the figure of $ 18 per barrel for the product cost published in SASOL's 1999 annual report it can be seen that continued improvements are required to decrease the operating costs of coal liquefaction towards the above-mentioned target. The capital charges for future coal-based operations would be site specific. Perhaps the benchmark should be those locations that use coal as a competitive feedstock for other synthesis gas-based processes, such as methanol or ammonia production. These locations may also be considered as a potential source of syngas for a Fischer – Tropsch based operation. In addition, there is synergy between various syngas users, e.g., ammonia and methanol synthesis.

SASOL has demonstrated that coal liquefaction using HTFT technology can be commercially viable, given a number of prerequisites. Firstly, such plants are capital intensive and require very large economies of scale to be viable. Secondly, higher value products other than liquid fuels must also be produced. Potential petrochemical products are light olefins (ethylene and propene) and various linear α-olefins, such as 1-butene, 1-pentene, 1-hexene, 1-heptene, and 1-octene. Alcohols are another important coproduct. Depending on the source of gasification technology, there are a number of gasifier byproducts that may also play a role. SASOL, for example, uses Lurgi Coal Gasifier, which produce valuable byproducts such as ammonia, phenol, cresol, etc. Advances in HTFT technology have, however, decreased the capital cost considerably since the CFB reactors, originally used in Secunda plants, were replaced by the SASOL Advanced Synthol reactors. In addition the energy efficiency of the Fischer – Tropsch process has been dramatically improved by recent technology developments. The Fischer – Tropsch unit is now also a large steam exporter substantially decreasing the need to generate high-pressure steam from coal. Cogeneration of power may also be an option at some locations.

Another aspect to consider are the recent developments in low temperature Fischer – Tropsch (LTFT) technologies. This results in considerable simplification of the primary product recovery and refining processes. The simplification leads to further decreases in the capital costs allowing viable applications at smaller plant capacities when compared to the HTFT route. At SASOL's Sasolburg site coproduction of methanol and hydrogen for ammonia production and refinery uses has been shown to produce synergistic benefits. The choice between HTFT and LTFT technologies is decisively determined by the desired products. The potential products from the various Fischer – Tropsch technologies are discussed in Section 2.2.6.

3. Direct Coal Liquefaction

3.1. Mechanisms

Because the exact structure of coal is unknown, understanding and close control of the processes by which coal is converted to liquids are difficult. The available structural information pertains predominantly to the vitrinite maceral, the most abundant organic coal constituent. Attempts to describe the vitrinite structure have focused either on the concept of an "average" structure, which embodies the measurable chemical parameters of vitrinite [135], [136], or on a less rigidly defined concept in which the maceral is considered to consist of a three-dimensional macromolecular network that can accommodate lower molecular mass species in open and closed pores [137–139].

Bituminous coal consists of highly substituted, cyclical carbon structures of one or more condensed rings linked by alkyl or ether (oxygen or sulfur) bridges. Low-rank coals contain a higher proportion of oxygen groups. With increasing rank, progressively fewer functional groups are present and the ring system becomes more polycondensed [140].

Uncatalyzed liquefaction is considered to be a pyrolytic process; the bridges linking the cyclical units are ruptured when heated to 400 – 450 °C. Ether linkages are cleaved first [141–143] and then methylene bridges [144–146]. In the early stages of liquefaction, hydroxyl groups are apparently lost more slowly than ether oxygen [147], [148]. Organic sulfur and oxygen are lost at similar rates [148], [149].

Bond rupture liberates free radicals, which can be stabilized by the addition of a hydrogen atom; the low molecular mass fragments are then dispersed in the solvent. If hydrogen capture does not occur, the radicals can combine to form stable, high molecular mass products, leading ultimately to char or coke formation (Fig. 11).

It is well recognized that such retrogressive reactions occur to some extent during coal liquefaction and that they have a negative impact on the liquid yield [150], [151]. It has become increasingly clear that retrogressive reactions substantially hinder the liquefaction of low-rank coals and that oxygen-containing functional groups in the coal structure are major actors in these retrogressive reactions. Carboxyl functions have been implicated with the cross-linking of coals during heating at relatively low temperatures [152–156]. Benzyl-type radicals can lead to retrogressive reactions and these reactions can be induced by decomposition of the oxygen-containing functional groups and condensation of the polyhydroxyl structure, such as aromatic polyphenols and aromatic carboxylic acids [157], [158]. A two-stage liquefaction, using a lower preheating temperature, is advantageous compared with one-stage liquefaction for the same reaction time [159], [160].

In addition, the oil yield was successfully increased by demineralization [159], solvent swelling [161], [162], or alkylation of coal [163], [164].

Liquefaction, therefore, depends critically on a supply of hydrogen atoms commensurate with the rate of free-radical formation, which is a function of coal structure and reaction temperature. Hydrogen sources are the liquefaction solvent, the coal, or H_2 gas. A new mechanism was proposed for hydrogen donation and cleavage of relatively strong bonds, involving a solvent-assisted process [165], [166]. This mechanism, called radical hydrogen transfer (RHT), is illustrated at the bottom of Figure 12. According to this reaction pathway, H-atoms transfer occurs through solvent-derived radicals to ipso-positions of the coal matrix which leads to the scission of the strong bonds in the coal structure. This pathway also provides the possibility that the selectivity in coal liquefaction might be controlled by tailoring the solvent medium appropriately [167]. Other exciting developments include discovery of new bond-breaking chemistry, such as the use of water to cleave refractory diaryl ether covalent bonds [168–170].

A major limitation to understanding the process of coal liquefaction is the lack of a realistic working model of the coal structure. Recent studies emphasize the importance of noncovalent bonds connecting the constituent macromolecules through their polar groups. Examples of these bonds are hydrogen bonds, charge-transfer interactions, cationic bridges, and layered stacking aromatic planes, which are responsible for low solubility, facile coking of coal

Figure 11. Representation of processes occurring during direct coal liquefaction; structures are representations only and are hexagonal combinations of aromatic and nonaromatic rings

components, and limited access to solid catalysts [171–175].

Although progress in improving the direct coal liquefaction process in the 1990s has been particularly significant, the fundamentals of the physical and chemical processes during the coal liquefaction are still incompletely understood [176]. A comprehensively knowledge of basic coal structure must be acquired for the effective development of coal liquefaction [177–182].

3.2. Liquefaction Products

The initially solubilized coal is high in molecular mass and cannot be distilled. Extended thermal or catalytic reaction is necessary for the production of distillates. In all cases a distribution of products is obtained that includes light gases, distillate liquids, and nondistillable liquids, which may be solid at room temperature.

The nondistillable products are usually characterized by solvent fractionation, using techniques developed for the petroleum industry. The liquids are separated on the basis of solubility into oils (soluble in pentane or another light alkane) and asphaltenes (benzene-soluble and pentane-insoluble). A third category, not used in petroleum processing, is preasphaltenes (pyridine-soluble and benzene-insoluble); this category is applied to coal liquids [183]. The distinction between the three fractions is based solely on solubility and has no chemical significance. The quantities of the fractions isolated from coal liquids are sensitive to the solvent separation procedure [184–187].

The chemical character of asphaltenes depends on the structure of the parent coal and on the processing history. Long hydrotreatment increases aromaticity and reduces the concentration of polar functional groups and molecular mass [188–190].

Figure 12. Conventional coal liquefaction mechanism and solvent-mediated hydrogenolysis [165]

Figure 13. Reaction of H-donors with coal [149]
○ Tetralin; □ Dihydrophenanthrene

These considerations are often ignored in the literature, where, for example, kinetic models are based on the erroneous assumption that a solubility fraction behaves as a single compound.

3.3. Solvents

The solvent used in coal liquefaction serves a number of important purposes. It provides a transport medium for the coal and facilitates heat transfer. During reaction it serves as an important source of transferable hydrogen, and it disperses the liquefaction products.

Most processes are designed to be independent of external sources of solvent and hydrogen gas. Therefore, the solvent must be derived entirely from the liquefaction products for recycle and produced in sufficient quantity and of suitable quality to sustain continuous operation. A

sufficient degree of freedom within the process is necessary to control recycle solvent composition. Much research has been devoted to the reactions of solvents with coal to identify those products that improve liquefaction so that they can be selectively separated for recycle or generated in an additional process stage.

The stipulation for liquefaction processes to generate their own solvent has been subject to reevaluation. The co-processing of coals with heavy hydrocarbon feeds, such as tar sands bitumen, shale oil kerogen, heavy petroleum crudes, or petroleum residuals, can upgrade the hydrocarbon feedstock to distillate products as well as produce liquids from coal [191–195], [196–204]. Other benefits include simultaneous reductions in the concentrations of metals, sulfur, and asphaltenes (see Table 17). Co-processing eliminates the need for recycling, and is consequently more economical than integrated liquefaction.

3.3.1. Hydrogen Donors

The solvent components that are the most effective hydrogen-donor compounds (H-donors) are those with a *partially hydrogenated aromatic structure* [141], [183], [205–209]. The hydroaromatic hydrogens are readily abstracted, giving rise to stable aromatic compounds and stabilizing the coal free radicals [210].

where R· represents any group fragmented from the coal structure

Electron spin resonance (ESR) spectrometry permits direct observation of free radicals in coal and in its liquefaction products [209], [211], [212]. Although the mechanistic significance of ESR data is debatable [209], the free-radical population has been shown to be substantially lowered by active H-donors.

∗ Conversion: coal 89 %, residuum 76 %.
∗∗ American Petroleum Institute.

The value of hydrogen-donor compounds has long been recognized, and their activity is related to the degree of saturation and to the number of condensed rings [2], [15], [27]. Complete saturation produces stable naphthenic compounds (e.g., decahydronaphthalene) that are poor H-donors compared to partially saturated compounds (e.g., tetrahydronaphthalene, **1**) [141], [208]. In turn, 9,10-dihydrophenanthrene (**3**) is a more active H-donor than tetrahydronaphthalene (see Fig. 13).

Polycyclic compounds are easily hydrogenated or dehydrogenated. Pyrene (**6**) is readily converted to dihydropyrene (**5**) during coal liquefaction (see Fig. 14, [213]). Although the reaction can proceed thermally, it is enhanced by catalysts [214–216]. Thus, polycyclic aromatics can be converted to hydrogen donors in situ and provide hydrogen via a hydrogenation – dehydrogenation cycle. However, naphthalene (**2**) is not converted in significant quantity to tetrahydronaphthalene (**1**) under liquefaction conditions [183], [217]. Dihydropyrene (**5**) can also be formed by the transfer of labile hydrogen from coal [213]. The redistribution of hydrogen by repeated hydrogenation and dehydrogenation is called *hydrogen shuttling* [208].

The presence of solvent can aid in the transmission of H-atoms, generated at catalyst sites, to the coal. The effectiveness of hydrogen distribution by this means will be determined by the solvent composition and it will be accentuated when a significant concentration of H-shuttlers (e.g., polycondensed aromatics) is present. The

H-atoms produced by catalytic dissociation will increase the pool of available hydrogen within the coal or coal – solvent system and will be available for hydrogenation of aromatics, promotion of bond cleavage reactions, and stabilization of radicals [214–216], [218–224].

Figure 14. Formation of dihydropyrene during liquefaction [213]
● Hydrogen atmosphere; ■ Argon atmosphere

Certain *heterocyclic nitrogen compounds,* such as piperidine and 1,2,3,4-tetrahydroquinoline, are effective liquefaction solvents [225–228]. They give high coal conversions under mild conditions. However, these compounds are easily and irreversibly incorporated into the products. Such processes evidently involve more than simple hydrogen transfer. Liquefaction solvents typically contain 10 – 15 % nitrogen compounds, and their presence may be important to coal conversion [229].

3.3.2. Coal Conversion and Hydrogen Transfer

Coal liquefaction can be considered to take place in two kinetically distinct stages. First, part of the coal is rapidly converted with low hydrogen consumption. This typically occurs in 5 min or less above 400 °C, with a hydrogen consumption of 0.2 – 0.5 wt % of the coal. Subsequent conversion is gradual and consumes much more hydrogen [141], [208], [230]. Attempts have been made to separate these processes by using two reactors under different conditions (see Section 3.9.6).

The first-stage conversion depends on the structure of the coal; the bulk of the hydrogen demand is probably satisfied by the coal itself. Despite some opposing evidence [208], conversion and product distribution are apparently strongly affected by the composition of the solvent, even at very short reaction times (Fig. 15); conversion increases with increasing H-donor concentration [230–232]. The presence of selected nondistillable liquids can improve both conversion and distillate yield, while allowing a reduction in reaction severity [233]. Reactions that occur during the first stages of coal dissolution may strongly influence the extent of subsequent conversion and the product selectivity [217].

Second-stage conversion is more clearly dependent on H-donor concentration (Fig. 16). During prolonged reaction in a donor-limited system, conversion may be reduced because of the prevalence of condensation reactions [234]. A high solvent : coal ratio can also retard condensation reactions by increasing H-donor capacity and by diluting the dissolved coal [230] (see Fig. 17). In actual operation, practical considerations limit the ratio to values between 1.5 and 2.0.

Figure 17. Effect of solvent : coal ratio on subbituminous coal conversion at short times [217]
□ Hydrogenated solvent; ○ Nonhydrogenated solvent
∗maf = moisture and ash-free.

The thermally initiated reactions of coal, especially of low-rank coals, can take place very rapidly at lower temperature producing free radicals. Whether these free radicals are stabilized by hydrogenation or by retrogressive reactions is the critical point in the liquefaction of low-rank coals. The important factors which have significant impact on the hydrogenation or retrogressive reactions are reaction conditions (temperature, H_2 pressure, and reaction time), solvents, and catalysts. The reaction conditions have been studied by many researchers and the procedures for single-staged liquefaction (SSL), temperature-staged liquefaction (TSL), and temperature-programmed liquefaction (TPL) have been proposed [235–237]. For catalytic liquefaction of a subbituminous coal using a dispersed molybdenum catalyst the TPL was found to be superior to SSL in terms of higher conversion and oil yield (see Table 18). Low-temperature catalytic pretreatment or preconversion may be a promising approach to enhance coal conversion due to the suppression of retrogressive reactions.

3.3.3. Interactive Solvent Effects

Coal-derived solvents are highly complex mixtures containing compounds that can beneficially or adversely influence liquefaction. The effectiveness of H-donors can be augmented by the presence of compounds that are strong solvents, such as phenols [209], [238–242]. Combinations of certain solvents act synergistically, e.g., mixtures of tetrahydronaphthalene and pyrene [233]. Process solvent blends, e.g., distillate with nondistillate, can offer advantages to coal conversion because of improved hydrogen transfer or physical solvation [243–248].

The partition of solvent components between the vapor and liquid phase could strongly affect the degree to which they can contact other liquid and solid reactants (coal and catalyst) in the slurry phase. In flow reactors, the stripping of lower boiling fractions by the gas stream will lead to a reduced residence time of these fractions relative to the high-boiling fractions. By reducing the boiling range of the recycle solvent in a continuous flow reactor, the residence time of the high-boiling reactants was selectively increased, leading to an increased oil yield [249–251] (see Fig. 18). An analysis of the composi-

tion of the liquid in the reactors under liquefaction conditions confirmed that the increase in gas flow rate (GFR) enhanced remarkably the stripping of the solvent fraction in the feed slurry and the lighter fraction derived from the coal. This results in an increased actual residence time of the liquids consisting of the concentrated catalyst and heavy fractions [251], [252]. Among the high-boiling point components, the hydrocarbon fractions of the recycle solvent can enhance liquefaction, whereas the heterocyclic fractions can be detrimental.

∗∗ THF = tetrahydrofuran.

Among high-boiling components, the hydrocarbon fractions of recycle solvents can enhance liquefaction, whereas the heterocyclic fractions can be detrimental [253]. The tendency to char is strongly affected by chemical composition [254]. If a solvent contains too high a concentration of constituents that tend to carbonize, such as polyfunctional components, condensation reactions predominate, which result in low conversion [246], [255].

3.3.4. Side Reactions of Solvents

In addition to performing the functions described in Section 3.3.1, solvent components can undergo isomerization, cracking, and polymerization. The resulting losses can lead to solvent imbalance [256–258].

The incorporation of nitrogen-containing solvents into the liquefaction products has already been mentioned (see Section 3.3.1) [209]. Tetrahydronaphthalene dimerizes and is converted to methylindan and butylbenzene [141], [230], [259–264]. The isomerization of hydroaromatic compounds is attributed to the presence of free radicals [265].

Figure 19. Effect of H-donor concentration on solvent side reactions [149]
Tetrahydronaphthalene concentration: ○ = 0 %; □ = 4 %; △ = 8 %; ▽ = 40 %

Even active H-donors, such as tetrahydronaphthalene and octahydrophenanthrene,

are readily incorporated into high molecular mass liquefaction products (see Table 19). The effect of tetrahydronaphthalene concentration on the extent of side reactions during liquefaction has been studied by mixing it with 2-methylnaphthalene, *p*-cresol, and 4-picoline [149], [266]. At low tetrahydronaphthalene concentration, *p*-cresol forms ethyl and dimethyl phenols (see Fig. 19); 2-methylnaphthalene dimerizes and condenses with *p*-cresol. Reaction with coal can result in solvent alkylation. In pyrene, as many as 1 in 60 of the carbon atoms in coal can participate in the formation of methyl and dimethyl pyrenes [213], [266].

3.4. Coal Composition

The behavior of coal during liquefaction is usually governed by rank, petrographic composition, and inorganic constituents [267]. The macerals of the vitrinite group, which constitutes >80 vol % of the organic content of most coals and of the liptinite group, are generally accepted to be the most reactive in liquefaction. Inertinite macerals, with certain exceptions, are much less reactive [268], [269].

Figure 20. Dependence of conversion on coal rank [270]
∗ dmmf = dry, mineral matter-free.

3.4.1. Coal Rank

The influence of rank on the conversion of a series of British coals in a poor H-donor solvent is shown in Figure 20 [270], [271]. Mid-rank coals (ca. 83 – 88 % maf carbon) liquefy most readily, whereas coals of higher rank are almost inert [272]. Lower rank coals require an additional source of hydrogen (H_2 or H-donor) to attain high conversion levels, as shown in Figure 21.

Figure 21. Dependence of conversion on coal rank and hydrogen source [213]
○ Pyrene solvent, inert atmosphere; □ Pyrene solvent, hydrogen atmosphere; △ Tetralin-containing solvent, hydrogen atmosphere
∗ maf = moisture- and ash-free.

Although this account of rank dependence is generally accepted, differences of opinion exist concerning the liquefaction behavior of low-rank coals [15], [268], [269], [273].

3.4.2. Bituminous Coal

A strong correlation appears to exist between the liquefaction and coking properties of bituminous coals [274–277]. Low-molecular mass, hydrogen-rich bitumens present in coal may serve as H-donors and as solvents for molecular fragments as they are liberated [276], [278].

The yield of liquids extractable in chloroform, which reaches a maximum at 85 – 90 % moisture- and ash-free carbon [279], correlates with the fluid properties of the coal [278], [280]. The yields of pyridine and quinoline extracts show a similar correlation with coal fluidity

[281]. Such extraction can destroy the fluid behavior of the coal [3]. Liquefaction yields in nondonor systems are related to the fluid characteristics of the coal, decreasing as the softening point of the coal increases. In an H-donor solvent, high conversions are obtained for most bituminous coals [274]. Coals with relatively low softening points (commensurate with a high content of chloroform-extractable liquids) do not require H-donor solvents for high conversions; the necessary hydrogen can be provided by internal redistribution. The removal of low molecular mass liquids by extraction reduces coal conversion, especially in nondonor systems [282].

3.4.3. Low-Rank Coal

The liquefaction behavior of subbituminous coals and lignites differs from that of bituminous coals. Lignites tend to be more readily converted in moist mixtures of carbon monoxide and hydrogen than in hydrogen alone (see Section 3.6) [283]. Liquefaction of low-rank coals has caused pumping difficulties because of the high viscosity of the residual products. Such problems can sometimes be surmounted by increasing the liquefaction residence time [210] or by adding disposable catalysts (see Section 3.7.2).

Another source of difficulty is the formation of calcium carbonate deposits. Lignites and subbituminous coals can contain up to 3 wt % of calcium, present as humic acid salts. The liquefaction process liberates calcium oxide, which reacts with carbon dioxide to form calcium carbonate. The carbonate can deposit on reactor walls or grow and accumulate in the reactor and other units. Accumulation can be prevented by periodic withdrawal of solids from the reactor or by pretreating the coal with sulfur dioxide gas. Deposits do not form from the resulting stable calcium salts, such as calcium sulfate [210], [284], [285].

Compared with bituminous coals, low-rank coals contain less sulfur and more moisture and organic oxygen. High oxygen content has been associated with the absence of plastic properties, which precludes the liquefaction mechanisms available to bituminous coals [276]. Fluid properties are related to oxygen cross-linking that may be inherent in low-rank, high-oxygen coals [286] or may arise from mild energy input [287], [288].

Low-rank coals convert more slowly and incompletely than bituminous coals. They are more sensitive to solvent H-donor concentration and require more severe reaction conditions to maximize liquid yield [210], [255], [276], [289]. Formation of water (from organic oxygen) and gas is high, accounting for greater hydrogen consumption [289]. Most of the oxygen in low-rank coals forms carbon oxides on liquefaction (above 400 °C) [290].

Although total liquid yield tend to decrease with decreasing rank, the proportion of low-boiling distillates increases [291]. Early German work suggested that, compared to bituminous coals, the low-rank coals contained smaller polynuclear units [15]. The liquids produced by bituminous and subbituminous coal liquefaction have been analyzed in detail [291]. The subbituminous coal products were more volatile, contained more saturated hydrocarbons, were less aromatic, and had a higher hydrogen content and fewer heteroatoms.

3.4.4. Coal Drying and Oxidation

Drying or storage in an oxidizing atmosphere (aging or weathering) can deleteriously affect coal liquefaction behavior [276]. Even exposure to mild oxidizing conditions can reduce yields, partly because of polymerization of coal-derived liquids [213], [292–295]. Oxidation similarly reduces the yield of pyrolysis liquids while increasing their aromaticity and molecular mass [296], [297].

Oxidation of bituminous coals adversely affects plastic properties (see Fig. 22) and the yield of extractable liquids (as shown by the following data) [2], [298–302]:

Weathering time, d	Mass fraction extracted in tetrahydrofuran (dmmf ∗), %
0	21.3
5	19.6
35	18.3
56	14.5

∗ dmmf = dry, mineral matter-free.

Plastic properties can be restored by reduction [298].

Figure 22. Reduction in coal fluidity with progressive oxidation [299]
∗ ddpm = dial divisions per minute.

The mechanism of coal oxidation has been studied [299], [301–303]. Oxidation introduces ether, carbonyl, carboxyl, and phenolic groups, which results in the loss of aliphatic structures. The conditions of oxidation and the structure of the coal appear to have a strong influence on the extent of oxygen uptake and the functional group distribution. The reduction in plastic properties has been attributed to formation of stable ether cross-links and to loss of aliphatic groups [301], [302]. Cross-linking may also result from functional group condensations or from the formation of unstable ethers, which proceed to cleave at still higher temperature, leading to carbon – carbon bond formation [276]. The oxidation tendency generally increases with decreasing rank, as can be seen from Table 20 [298], [303].

A drying process, with minimal effect on the reactivity of coal, is important in coal liquefaction studies [304]. Drying of coal can cause an irreversible change in the pore structure such as collapse of pores, which could limit the accessibility of the reacting components during liquefaction [305–311]. A negative impact of severe oxidation on coal liquefaction is considered to arise from the significantly increased oxygen functionality which enhances the cross-link formation in the early stage of coal liquefaction.

Drying lignites before liquefaction lowers the yield of light oil products, possibly because of oxidation [304–310], [313–315]. These decreases in yield can be reduced by driving off moisture after the coal is slurried in the liquefaction solvent [312], [316].

3.5. Gaseous Hydrogen

Reaction under hydrogen pressure provides a source of stabilizing hydrogen in addition to that available from the solvent and the coal. The consumption of hydrogen gas increases with decreasing H-donor solvent concentration, even at short reaction time, and the presence of hydrogen gas can alleviate constraints on solvent quality [317].

Gaseous hydrogen may react directly with coal or through intermediate solvent hydrogenation. Partial hydrogenation of compounds, such as quinoline and pyrene, can produce active H-donors by thermal reaction [217], [318], but catalytic processes are regarded as being of primary importance (see Section 3.7). Molecular hydrogen may also participate in free-radical reactions, competing with donor hydrogen and promoting the cracking of C – C bonds [143].

3.6. Liquefaction in $CO - H_2O$ and $CO - H_2 - H_2O$

Since the economy of the direct coal liquefaction process using high-pressure pure molecular hydrogen is aggravated by the cost of hydrogen production, development of a process using an alternate hydrogen source is of great importance [319–329]. Excellent accounts of coal liquefaction in mixtures of water with carbon monoxide or with synthesis gas are available [183], [315], [330]. Low-rank coals give higher yields in a mixture of water and carbon monoxide than in hydrogen. This advantage decreases with increasing coal rank; for bituminous coals hydrogen is superior [283], [331]. Reactions of some Victorian brown coals with $CO - H_2O$ in the presence of sodium aluminate have been shown to give very high conversions to products (THF solubles) under mild conditions (see Table 21). The influence of water loading, of reaction time and temperature, of sodium aluminate concentration, of gas composition, and of CO partial pressure have been investigated [326]. Oil yield was significantly higher for $CO - H_2O$ than for H_2 – tetralin in the liquefaction of brown coal.

Table 20. Effect of oxidation on oxygen distribution [303]

Carbon	Oxygen gain, g/kg dry coal						
in coal, wt %	In gas			In solid			Total
	CO_2	CO	H_2O	COOH	OH	C=O

The CO – H_2O system requires a basic catalyst, such as an alkaline component or a basic nitrogen-containing compound in the liquefaction solvent. Because most lignites contain high proportions of Na^+ and Ca^{2+} ions, they possess an indigenous catalyst. The addition of sodium formate, alkali carbonates, iron oxide, or metal chlorides promotes activity [332].

Carbon monoxide may function by reducing the carbonyl groups in the coal, thus minimizing condensation reactions. The mechanism may involve formate intermediates produced by the reaction of CO and H_2O with alkali compounds or nitrogen bases [322–325]. Above ca. 400 °C, the formate begins to decompose to produce carbon monoxide and molecular hydrogen. The fact that the latter is less reactive than the formate hydrogen contributes to the reduced effectiveness of CO –water reactions at higher temperature [315].

Hydrogen is also supplied by the water – gas shift reaction (see Section 2.1.2). Hydrogenolysis by nascent hydrogen from the shift reaction may be one of the reasons for effective coal liquefaction [333].

For economic reasons, there is an incentive to replace carbon monoxide by less expensive synthesis gas. Conversion of lignites and subbituminous and bituminous coals in CO – H_2 – H_2O mixtures is different than in CO – H_2O [315]. The highest reactivities were obtained with high-volatile bituminous coals (hvc) having high mineral and sulfur contents. The reactivity of subbituminous coals correlated well with the sum of their iron, sulfur, and alkali-metal contents, and the liquefaction of lignite was greatly improved by the addition of pyrite. Increased consumption of CO indicated that pyrite also catalyzes the water – gas shift reaction. A synthetic pyrite of large surface area was found to be one of the most excellent catalyst precursors for the liquefaction of Australian brown coals in the CO – H_2 – H_2O system. Similar results were obtained with a $Fe(CO)_5$ + S catalyst [326–328]. The presence of CO or H_2O may have a positive side effect in enhancing the dispersion of Mo catalysts [329].

The behavior of both H_2 and CO is affected by mineral matter and added catalysts. However,

these gases function differently. Carbon monoxide is most effective below 400 °C, supposedly by inhibiting cross-linking reactions. Hydrogen is more reactive at higher temperature, participating in hydrocracking reactions that can increase oil yield and reduce product viscosity. Although the application of CO-containing gases has been the subject of numerous liquefaction studies, this approach has never emerged as a serious candidate for large-scale development.

3.7. Catalysis

The use of extraneously added catalyst is essential to developing a viable liquefaction process. Catalysts have been used either in the dispersed form in the coal – solvent slurry, or as supported metals in fixed or ebullated bed reactors [334–338]. The former are used to promote the primary hydrogenation of coal, while the latter are most effective for upgrading of coal-derived liquids. Improved performance can be realized both during primary coal liquefaction and coal liquids upgrading by using suitable catalysts. The advantages of application of catalysts include accommodation of a wider range of coal feeds, higher selectivity to liquid products with reduced light gas yield, reduced reaction severity, and improved product quality. Effective catalysis can also help to reduce investment and operating costs through lowering the reaction severity. More efficient use of hydrogen can greatly improve process economics [339]. The following cost analysis (1998 – 2000) gives the range for the HTI-Coal process, NEDOL process, and Improved BCL process (see Section 3.9).

Capital cost (of coal)	\$ 170 200 – 199 000 t^{-1} d^{-1}
Liquid products	0.53 – 0.71 m^3/t of coal
Capital cost (of syncrude)	\$ 248 000 – 372 000 m^{-3} d^{-1}
Capital cost distribution	
Liquefaction	39 – 49 %
Hydrogen manufacture and cleanup	19 – 32 %
Others (power, utilities, tankage, and offsite facilities)	19 – 42 %
Total costs	
Coal	20 – 27 %
Capital	45 – 57 %
Operations	17 – 35 %

Pilot plant tests at Wilsonville in the United States have demonstrated that the use of dispersed catalysts could be superior to supported catalysts for primary liquefaction of coal, particularly low-rank coals such as subbituminous coals or lignite [340], [341]. Liquefaction processing and economics may be improved more efficiently through the development and appropriate application of highly dispersed catalysts [342].

3.7.1. Mechanisms

Coal liquefaction catalysts function in a number of ways as shown in Figure 23. In the initial stage of coal liquefaction thermal decomposition of coal occurs to give free radicals. Free radicals thus formed from coal can be stabilized by hydrogen abstraction from either hydrogen donor substances or molecular hydrogen activated by a catalyst. Hydrogenation of aromatic component and hydrocracking of C – C bonds in the coal-derived initial products could result in a decrease in their molecular mass to give lighter oil fractions. In the early stages of coal liquefaction, promoting hydrogenation reactions appears to be the most critical requirement.

Liquefaction with a highly dispersed iron catalyst in tetralin and tetralin – naphthalene mixtures suggests that the most significant role of the catalyst is to activate molecular hydrogen and transfer it to coal fragment radicals [343]. Catalysts may indirectly increase hydrogen transfer to the coal by hydrogenating solvent species to produce H-donor compounds. Consequently, retrogressive reactions of thermally decomposed coal fragment radicals are suppressed and increased coal conversion and yield of oil fractions are obtained.

Figure 23. Catalyst functions in direct coal liquefaction

Iron-based catalysts exhibit a much lower activity for the heteroatom removing reactions,

such as hydrodesulfurization (HDS) and hydrodenitrogenation (HDN) than molybdenum-based catalyst. Heteroatoms, such as O, S, and N, in aromatic rings require sulfided Ni – Mo or Co – Mo catalysts for their expensive removal to the levels experienced in petroleum refining [338].

Supported catalysts, consisting of metals deposited on high surface area supports, have the advantage of high dispersion at relatively low metal concentrations. However, a large portion of the metal may be contained in pores whose size restricts the access of large molecules, thereby rendering those site ineffective for facilitating the dissolution of solid coal particles. Consequently, supported catalysts are more suitable for hydroprocessing of distillate liquids.

3.7.2. Disposable Catalysts

Disposable (i.e., once-through) catalysts are materials whose recovery is not economically essential. Catalyst cost is low because the material is cheap or because it is highly active at low concentration.

Some coal minerals are catalytically active [344], but the content and composition of these components are too variable for stable process operation. However, research has been conducted on mineral matter catalysis to identify prospective disposable catalysts. Dispersed catalysts generally have very little internal porosity and the active sites are on the exterior surfaces of the particles. These catalysts are more effective for promoting the initial conversion of coal. A variety of metals have been tested for possible use as dispersed catalysts over the years, including molybdenum, iron, tungsten, cobalt, nickel, tin, zinc, and mixtures of these metals. The high dispersion of the catalyst makes recovery difficult if not impossible, and therefore the cost of the catalyst is a critical factor.

Pyrite and other iron compounds have attracted widespread interest as disposable catalysts [345], [334]. Molybdenum and tin, used in Germany during the 1930s and 1940s, were replaced by less active, cheaper iron ores [15], [346]. In the liquefaction of low-rank coals, molybdenum (0.2 wt % daf) was as effective as a high concentration of pyrite (2.5 wt % daf); however, the latter was preferred because of cost [347, part 2]. More recently, there has been renewed interest in the use of iron-based catalysts as disposable catalysts because of economic and environmental benefits. Highly active iron-based catalysts have been extensively investigated in Japan and the United States [335], [342].

Clays. The mineral content of most coals consists largely of clays, which have complex polymeric aluminosilicate structures (→ Clays). The hydroxyl groups attached to Si and Al are strongly acidic and provide active sites for catalysis. Kaolinite and montmorillonite catalyze hydrogen transfer between hydroaromatic and aromatic compounds, and kaolinite increases the conversion of coal to gas and benzene-soluble products [348], [349]. Natural clay minerals may possess cracking activity.

Iron Sulfides. The activity of iron catalysts is generally low, necessitating the use of relatively high concentrations (several wt % on daf coal) of iron. A variety of methods have been employed to increase the activity of iron-based catalysts [350]. Catalyst precursors have been introduced by physically mixing very small particles into the coal – solvent slurry [351–361], by addition of iron sulfides precipitated from aqueous solutions [362], by addition of the catalyst in oil-soluble forms [363–369], and by impregnation of the feed coal with water-soluble compounds [370–374].

The activity of iron based catalyst depends on their composition and the extent of their dispersion. The extent of dispersion is directly related to the catalyst effectiveness. Until the coal is dissolved, there is no available mechanism by which reactants can be transported to the catalyst, and hence the basic requirement is to transport the catalyst to the reacting species. Some progresses are being made in the development of techniques to determine particle size and size distribution [375].

The synthesis of nanometer size catalyst particles could provide a means to enhance the activity of dispersed iron-based catalysts. Several techniques have been used to produce this type of precursor, including flame pyrolysis [352], laser pyrolysis [357], and a hydrothermal process [358]. The flame pyrolysis of metal chloride vapors has been used to produce aerosol oxides

with particle diameter of < 50 nm and surface areas of $20-50\ m^2/g$. Iron oxide particles generated by this technique have demonstrated a high catalytic activity for the liquefaction of bituminous coal, resulting in conversions only slightly lower than obtained with a similarly produced molybdenum oxide [376].

Table 22. Effect of FeOOH mode of addition on coal conversion at 425 °C, 0.5 h, 1000 psig (6.9 MPa) (cold) of H_2, 5000 ppm Fe, 0.1 g of S added to 9.9 g of a 2 : 1 mixture of PANASOL* to coal [374]

A laser pyrolysis technique has been used to produce a variety of iron-based particles including two phases of iron carbide (Fe_3C and Fe_7C_3), two phases of iron nitride (Fe_3N and Fe_4N), an iron sulfide ($Fe_{1-X}S$), and α-iron. The particles were in the range of 4 – 20 nm in diameter. Experimental studies have shown that the carbides transform to pyrrhotite ($Fe_{1-X}S$) under liquefaction conditions and that the addition of sulfur appears to inhibit sintering. These particles have demonstrated moderate catalytic activity for the conversion of bituminous coal [377].

High activities have been reported for catalysts introduced as oil-soluble organometallic precursors, such as carbonyls and naphthenates [378], [363–370], [379]. The results of some studies indicate that, even with the soluble precursors, quite large crystallites or agglomerates can be formed during liquefaction and hence the potentially high dispersion is not maintained [335]. The use of an incipient wetness technique to impregnate the coal with Fe^{3+} from an aqueous solution has been shown to give high dispersion of the catalyst precursor on a coal substrate (see Table 22) [337], [374]. The coal matrix may also aid in maintaining the high dispersion of catalyst particles subsequent to the activation. As a catalyst loading of 2500 ppm the precipitate FeOOH yielded the same catalytic activity as 1500 ppm molybdenum, added as ammonium heptamolybdate (see Fig. 24) [337].

Another route to improving the activity of iron catalysts is to modify their composition. One approach has been to change the surface properties of hematite particles either by treating the precipitates with H_2SO_4 or by precipitating in the presence of sulfate anions, resulting in the formation of Fe_2O_3/SO_4^{2-} particles after calcination [232], [380–385]. Sulfated Fe_2O_3, SnO_2, and Mo/Fe_2O_3 have focused attention to the catalytic activities in coal liquefaction [380], [383]. The sulfate group is believed to be responsible for the superacidity of catalyst, and it can also help to prevent sintering of the catalyst particles, which may relate to their enhanced catalytic activities [380].

The effectiveness of iron-based catalyst can be greatly improved by the addition of small concentrations of molybdenum [383], [386–388]. The activity of Mo-added iron oxide aerosol catalysts was higher than that of supported Ni – Mo catalysts [388]. These fundamental studies have provided evidence for an increase in catalytic activity with decreasing iron particle size, decreas-

ing availability of sulfur donating species, and suppression of the crystal growth of iron sulfide. Elemental sulfur was often added with the iron oxide catalyst when low-sulfur coals were processed. Iron oxide can be converted to sulfide in situ and the active form of iron catalyst is generally believed to be a pyrrhotite [15], [17], [204], [345],[346], [389–399]. For the iron catalyst, the activity reached a maximum level at an S : Fe atomic ratio > 1. In many cases, the attainment of this phase relies upon in situ sulfiding, and there is scant information on the relative kinetics of dissolution and sulfiding reactions: the rate of conversion of the precursor to a sufficiently active form may, in some cases, be too slow to influence the process of coal dissolution. The mechanism of catalysis by iron sulfide is controversially discussed [204], [345], [389–405]. The roles of pyrite and pyrrhotite are unclear. Pyrrhotite is a nonstoichiometric mineral, which may be catalytically active: it has a variable number of lattice vacancies. The partial pressure of H_2S is important because it influences the concentration of metal vacancies [389], [400–403], [406]. Another mechanism suggests that sulfide minerals generate H_2S, which acts as a hydrogen donor and initiates the free-radical chain reactions [344], [403], [404]. In the working states, the active sites may be sulfate species formed on the surface of iron-based catalyst during the coal liquefaction, because the catalyst may be always exposed to oxidants in the reaction system [405].

Iron-based catalysts are used in Germany [24], [38], [39], [273], [408], Japan [41], [44], [342], [353–355], [407], [409][411] and the United States [22], [32], [347].

In the German IGOR process, a disposable iron catalyst known as "red mud" or Bayermasse is used at a concentration of ca. 4 – 6 wt % daf; it contains ca. 30 % iron(II) oxide and some abrasive material such as alumina [15], [39], [273], [407], [408]. Removal of inorganic matter before the liquefaction can afford processing benefits and extend the life of plant equipment [412]. The use of high concentrations of low-activity catalyst, often associated with abrasive material, may lead to operating problems.

In the NEDOL process of Japan, finely pulverized natural pyrite catalyst is used at a concentration of 2 – 3 wt % daf in the liquefaction of subbituminous or bituminous coal [409–411]. Natural pyrite was dried to 1.5 wt % moisture, and then finely pulverized to 0.7 μm particle size in the process solvent by a two-stage pulverizing method; to 2 μm by a ball mill in the first stage and then to 0.7 μm by an agitated beads mill in the second stage [409]. Finely pulverized pyrite catalyst increases coal conversion and the selective production of oils [413], [414]; milder operating conditions become possible and gas formation is reduced. Pyrite catalysis facilitated the continuous processing of low-rank coals [347], [347, part 2]. Highly active iron catalysts (synthetic γ-FeOOH and finely pulverized limonite ore) have been developed in the Improved BCL process of Japan for the liquefaction of brown coals [342], [353–355], [415]. Both catalysts are well dispersed in the coal – solvent slurry by pulverization in the process solvent to submicron particle size before the coal liquefaction. Synthetic γ-FeOOH (30 nm crystallite size) catalyst exhibits a high oil yield over 60 wt % in the liquefaction of Yallourn coal even at the catalyst loading of 0.3 wt % as Fe with partial recycling [415].

This γ-FeOOH catalyst can be transformed into the smaller crystallite size of pyrrhotites at lower temperatures around 250 °C by the addition of elemental sulfur (see Fig. 25). The amount of elemental sulfur added to the iron catalyst was controlled at 1.0 vol % of H_2S in the reactor in order to suppress both formation of less active troilite (FeS) and the crystal growth of pyrrotite particles [355].

Figure 25. Increase in crystallite size of pyrrhotites ($Fe_{1-X}S$) with sulfiding temperature at 0 min of holding time, 100 °C/min of heating rate, S : Fe ratio 2.0 with no coal in coal-derived solvent [355]

Table 23. Oil yield in the liquefaction of Yallourn coal with fresh or used * catalyst. Liquefaction conditions: 450 °C, 1 h, 200 g daf of Yallourn coal, 500 g of coal-derived solvent, 6.0 g of catalyst as Fe, 4.13 g of elemental sulfur (S : Fe = 1.2), 7.5 MPa initial H_2 pressure [416]

Catalyst		Pyrrhotite crystallite size, nm	Oil yield ** (wt % daf)

(Mt. Lyell, Australia)	used (CLB-THFI)	66	35.7

* CLB – THFI (THF insolubles in coal liquid bottoms) was employed as used catalyst.
** Oil yield: distillate oil (C_5 – 420 °C) yield.

Limonite ore consists of natural goethite (α-FeOOH), containing a considerable amount of hematite (α-Fe_2O_3). The hematite content can affect the catalytic activity: the lower the hematite content the higher the coal conversion. The activity of a finely pulverized limonite catalyst based on a specific limonite ore (named "Yandi Yellow") deposited in Australia, was comparable to that of γ-FeOOH catalyst (see Table 23). This limonite catalyst looks promising as a disposable catalyst in the commercial plant of BCL process due to its high catalytic activity, low pulverization cost, and abundant resources [416].

In HTI' s direct coal liquefaction process a proprietary dispersed superfine iron catalyst, "Gel Cat", is used [22]. Unfortunately, little information is available on its physical properties and chemical composition.

Nonferrous Metals. Molybdenum and tin are active liquefaction catalysts that were used in Germany before being replaced by cheaper, less active iron catalysts [346]. As little as 0.05 % molybdenum gave satisfactory results in brown coal liquefaction, provided that the coal alkalinity was first neutralized with sulfuric acid [417]. For bituminous coals, higher concentrations were required [15], [346].

In a plant at Billingham, United Kingdom, tin compounds and hydrochloric or hydroiodic acid proved to be active for bituminous coal liquefaction. The usual combination was 0.04 –0.06 % tin oxalate and 0.4 – 1.0 % ammonium chloride on the basis of feed. A similar catalyst was employed in some German plants, but because of scarcity and corrosion problems, was replaced by iron catalysts [15].

Many disposable liquefaction catalysts have been investigated, some in batch-autoclave experiments [418–426]. Tin promoted with a halogen was highly active; germanium oxide promoted with ammonium chloride and molybdenum, when applied by impregnation, were comparable [417]. Metal naphthenates were the most effective catalysts studied.

The influence of the mode of catalyst addition can be seen from Table 24 [421]. For molybdenum, the disulfide appears to be the active form, its effectiveness reaching a maximum when reaction with sulfur gives an S : Mo ratio of 2.0 [378].

Although iron remains the catalyst metal of choice because of cost and availability, the effectiveness of well dispersed molybdenum at low concentrations has led to much research on precursors based on that metal, and on possible recovery and recycle of the catalyst. Interest also remains in determining the chemical fate of precursors, and on using catalysis as a tool in further understanding the complex mechanism of coal liquefaction.

Extensive prior studies in the United States have demonstrated the potential of a dispersed molybdenum catalyst for coal liquefaction. In the Dow process, highly dispersed molybdenum was used as a disposable catalyst with partial recycling in the overflow of a hydrocyclone used for solids separation [30], [427]. Ammonium molybdate was added to the coal – solvent slurry as a water-in-oil emulsion at 100 – 200 mg per kilogram of slurry. Some molybdenum was recycled with the process solvent, increasing the concentration of active catalyst by a factor of 2.0 – 2.5. The microemulsion of molybdate is converted to very small particles of MoS_2 under

the reaction conditions, and a substantial portion of these species survives for recycling to the reactor.

Figure 26. Effect of reaction temperature on conversion of DECS-8 Wyodak coal with ATTM in the presence and absence of added water without using an organic solvent [429] Copyright (2000) with permission from Elsevier Science

The nonstoichiometry of molybdenum disulfide originating from ammonium tetrathiomolybdate (ATTM) is also of interest, since the exact composition may play a role in ATTM-catalyzed liquefaction [428]. The conditions used for impregnation can strongly influence catalyst dispersion and activity in dry catalytic hydrogenation with coal impregnated with ATTM. In particular, water removal after impregnation gave greatly improved dispersion of Mo, as evidenced by scanning electron microscoppy/energy dispersive X-ray spectroscopy. A strong promoting effect of water addition on catalytic conversion using ATTM was reported for the liquefaction of subbituminous coals at low temperature of 350 °C (see Fig. 26) [429]. Temperature-programmed liquefaction using ATTM with added water at 350 °C, followed by water removal and subsequent reaction at 400 °C gave good coal conversion and oil yield [430]. A plausible extension of the ATTM concept is the use of its tungsten analogue, ammonium tetrathiotungstate (ATTW), as a precursor [431], [432].

Another type of catalyst materials are the chlorides of transition metals, such as $ZnCl_2$ and $SnCl_4$ [433–438]. Also the combination of a mild superacid (CF_3-SO_3H) and iodine was studied. Iit was reported that the acid enhances the depolymerization of coal to asphaltenes and that the major effect of iodine is to hydrogenate and hydrocrack asphaltenes to oil [439]. These catalysts are primary Friedel – Crafts type catalysts, which because of their acidic function catalyze C – C bond cleavage. The corrosive nature and instability of these catalysts may exclude their practical application.

3.7.3. Supported Catalysts

Supported catalysts are used in the form of 1.5 mm or larger particles in a fixed-bed [15], [440] or ebullated-bed reactor [32–34], [334–336]. Because the catalyst pores provide virtually all of the active surface area, the catalyzed reactions probably do not directly involve the coal, but rather the solvent and the liquefaction products. In some processes, primary coal dissolution is carried out in a separate reactor; in

others, most of the coal may dissolve during passage through the preheater [183].

In the US H-coal process, Ni – Mo or Co – Mo/Al_2O_3 catalysts have been used in the ebullated-bed reactor. Ebullated-bed reactors provide for catalyst addition and withdrawal, thus maintaining activity during operation [5]. The performance and deactivation characteristics of catalyst used in the Wilsonville Advanced Coal Liquefaction Test Facility were examined [441–443]. Catalyst deactivation is due to the buildup of both carbonaceous deposit and contaminant metals; steam sintering is somewhat less important [444]. A great deal of research has been devoted to examining the deactivation of supported catalysts during coal dissolution and upgrading [445–450].

Carbon deposition is rapid during the first 30 – 50 h on stream and is accompanied by a loss of surface area (see Fig. 27) and pore volume [452], [453]. After this decline, catalyst activity changes more gradually. Deactivation by metal deposition is slower (see Fig. 28) [454], the chief contaminants being iron, titanium, and boron [455]. The metal precursors are organometallics or other soluble compounds. Particulate minerals apparently do not contribute directly to poisoning, which is caused primarily by carbonaceous deposits distributed throughout the catalyst particles [183], [454]. Deactivation by metals takes place through a shell-progressive mechanism [454]. Contaminant metals cause loss of intrinsic activity by covering active sites and also cause some minor permanent loss of pores due to the pore-mouth blockage. The metal deposits are concentrated in an outer layer of the aged catalysts and may cause deactivation of the catalyst due to slow diffusion through this barrier. Carbonaceous deposits cause deactivation presumably due to active-site coverage and yield a decrease in catalyst average pore size due to the filling of larger pores. Nitrogen compounds, aromatics, and phenols may act as precursors for carbon deposits [456], [448]. Sintering and metal losses are among the other causes of catalyst deactivation [455], [450].

The earliest coal liquefaction catalysts were designed for hydrofining petroleum distillates and were ineffective for high molecular mass coal liquids because of their small and easily clogged pores [417], [457]. Increasing the proportion of larger pores has improved activity [417], [458], [459]. Catalyst requirements are similar for upgrading coal liquids and high-boiling-point petroleum residues [460].

Calcium-doped Ni – Mo/Al_2O_3 with bimodal pore distribution has been developed as a secondary hydrogenation catalyst in the BCL process, which has been shown to have a stable activity for about 8000 h, included the 3400 h operations of a 50 t/d pilot plant in Australia [461–465]. Doping of alkaline-earth metals, such as Ca or Mg, modifies the acidic properties of the catalyst and decreases the carbonaceous deposition on the catalyst in the hydrotreating of coal-derived liquids [465–468]. The modification of the acidic properties of the catalyst could be an effective way to suppress its deactivation (see Fig. 29).

Continuous reactor tests performed by Amoco have shown that the activities of Ni – Mo/hydrous titanium oxide (HTO) catalysts were significantly greater than that of commercial Ni – Mo/Al_2O_3 catalysts for the second-stage upgrading of coal-derived residues [469–472]. The catalysts prepared from HTO-coated supports, containing one-tenth the active metals of commercial alumina-supported catalysts, have been found to exhibit high hydrogenation and desulfurization activities based on weight of Mo. HTO-coated support materials may offer a promising method to produce cost-effective catalysts with mechanical, physical, and catalytic properties tailored to specific direct liquefaction process applications [472].

The high activity of Ni – Mo catalyst supported on carbon nanoparticles with extremely high surface area and low density has been demonstrated (see Fig. 30) [473–481]. This high activity is attributed to the high dispersion of active metals on the KB carbon nanoparticles. These catalysts, being hollow carbon particles, have a very low density and can potentially be recovered from the coal liquefaction products by gravimetric separation. Various combinations of sulfides such as Fe – Ni and Fe – Mo can also be candidates for catalysts with higher activity and lower cost [480].

Removal of heteroatoms is another important consideration in catalytic upgrading of crude liquefied oils. The storage stability of crude liquefied oil should be improved by a hydrotreatment step in the coal liquefaction process, as the heteroatoms in liquefied oils can cause the forma-

tion of gum or sludge during storage or transportation to the oil refinery. In the current liquefaction processes, such as the IGOR+ process [24], the HTI process [482], and the Improved BCL process [46], [483], the crude liquefied oil in the gas phase of the high temperature – high pressure separator is directly introduced into a fixed-bed reactor and hydrotreated in the presence of an Ni – Mo/Al_2O_3 catalyst, so-called in-line hydrotreatment (see Section 3.8). Table 25 shows the improved oil yield and quality achieved by integrated refining in the IGOR process [408].

The catalyst deactivation in the hydrotreating of crude liquefied oil derived from the BCL process was examined with a commercial Ni – Mo/Al_2O_3 catalyst during the operation for 2000 h under model conditions with coexisting

gases, such as NH_3, H_2S, H_2O, CO, and H_2, at 15 MPa. It was reported that the service life of the catalyst was about a year, although the catalytic activity slightly decreased with process time [483]. No serious problems have been reported on the in-line hydrotreatment of crude liquefied oils with boiling points below 420 °C. The nitrogen and sulfur contents in liquefied oil could be reduced to a negligible level (< 10 ppm, see Table 26).

3.7.4. Molten Halide Catalysts

Acid-catalyzed coal depolymerization has been used as an analytical tool and a technique for liquefaction [183], [484], [485].

The process is different from those described in Sections 3.7.2 and 3.7.3. Bond cleavage is heterolytic rather than homolytic, probably involving carbocation formation. The reaction is faster and hydrogenation and hydrocracking reactions can be catalyzed at much lower temperature and hydrogen pressure. The most important catalysts are metal halides, especially zinc chloride, which is comparatively inexpensive and selective for liquids in the gasoline boiling range. Nitrogen and sulfur contents in the distillates are low.

Shell Oil Co. patented zinc halide catalysts for the hydroconversion of heavy petroleum fractions [486], [487]. Consolidation Coal Co. developed a coal liquefaction process that uses large quantities of molten zinc chloride (1 : 1 wt ratio of $ZnCl_2$: coal). Large proportions of catalyst are required to control product composition and to maintain activity. The catalyst is rapidly poisoned by NH_3 and H_2S liberated during hydrogenation and hydrocracking.

Despite its potential, the process has not been scaled up because of corrosion and zinc chloride recovery problems. Coal mineral matter constituents, particularly those containing potassium or sodium, can form stable eutectic salts with the melt. This can complicate recovery, especially for low-rank coals with high alkali content. Research was concentrated on the use of mild conditions and lower catalyst concentration [433–435].

3.8. Process Description

Direct liquefaction is the most efficient coal liquefaction route currently available. Its liquid products can be used for most stationary fuel applications. However, these products require further upgrading before being used directly as transportation fuels. This upgrading utilizes conventional petroleum industry techniques, allowing the products from a liquefaction plant to be blended into the feedstock streams of a petroleum refinery.

Direct liquefaction processes can conveniently be divided into two main groups, depending on whether the initial dissolution of the coal is separated from the conversion of the dissolved coal into distillable products. Single-stage direct liquefaction processes give distillates via the primary reaction system. Such processes may include integrated in-line hydrotreating, which is intended to upgrade the primary distillates without directly increasing the overall conversion. In the mid- to late 1960s, all available processes were single-stage [488]. Most development therefore continued to adopt a single-stage approach. Some developers added a second stage in the 1970s to increase the production of light oils.

The *single-stage processes* developed furthest are:

Kohleoel (Ruhrkohle, Germany)
NEDOL (NEDO and NCOL, Japan)
H-Coal (HRI, USA)
Exxon Donor Solvent (Exxon, USA)
SRC-I and II (Gulf Oil, USA)
Imhausen high-pressure (Germany)
Conoco zinc chloride (Conoco, USA)

Most of these have since been superseded and abandoned. Two exceptions are the Kohleoel and NEDOL processes, both of which are considered ready for commercialization by their developers. Several other processes were developed to a modest scale in USA. Other countries, notably Russia and Poland, also carried out R&D on single-stage liquefaction at a significant scale; the approaches adopted are believed to be similar in most respect to the Kohleoel process.

A *two-stage direct liquefaction process* is designed to give distillate products via two reaction systems. The primary function of the first stage is coal dissolution. This stage is operated either without a catalyst or with a disposable catalyst. After the solids, consisting of mineral matter and undissolved coal, are removed by deashing, the heavy coal liquids or coal liquid bottoms are hydrotreated in the secondary stage in the presence of a high-activity catalyst to produce additional distillate. Development of most two-stage direct coal liquefaction processes started after the first oil crises in the early 1970s. The developments were performed in many countries, but few processes were proceeded to pilot-plant scale.

The processes include:

Catalytic Two-stage Liquefaction (CTSL) (DOE and HRI, now HTI, USA)
HTI Coal (HTI, USA)
Liquid Solvent Extraction (LSE) (British Coal Corporation, UK)
Brown Coal Liquefaction (BCL) (NEDO and NBCL, Japan)
Consol Synthetic Fuel (CSF) (Consolidation Coal Co. , USA)
Lummus ITSL (Lummus Crest, USA)
Chevron Coal Liquefaction (CCLP) (Chevron, USA)
Kerr – McGee ITSL (Kerr – McGee, USA)
Solvolysis (Mitsubishi Heavy Industries, Japan)
Pyrosol (Saarbergwerke, Germany)
Amoco CC – ITSL (Amoco, USA)
Supercritical Gas Extraction (SGE) (British Coal Corporation, UK)

Only the CTSL, LSE, and BCL processes continued in development beyond the late 1980s. But somehow these surviving processes have evolved or revolved to single-stage processes because of the development of highly active, disposable catalysts and economical reasons.

A simplified block flow diagram of most direct coal liquefaction processes is shown in Figure 31. A slurry of pulverized dry coal in recycle solvent, containing sometimes coal liquid bottoms, is mixed and transferred through a fired preheater into the liquefaction reactors together with hydrogen and disposable catalyst. The reactors are maintained at a temperature of 400 – 470 °C and a pressure of 12 – 30 MPa. The temperature is normally controlled by addition of recycle gas. The effluent from the reactor is cooled, depressurized, and finally separated into gaseous, liquid, and bottom products. The major liquefaction products are liquids, which amount

to more than 50 wt % based on dry, ash-free coal (dafc).

Figure 31. Block diagram of direct coal liquefaction

The bottom product consists of mineral matter, undissolved coal, and bottoms which cannot be distilled by vacuum distillation. The bottoms may be recycled as a portion of the recycle solvent or sent to a solids separation unit. Use of filters, centrifuges, hydrocyclones, or solvent precipitation is required if the mineral matter and undissolved coal must be separated from the liquids. Pilot plant experience has demonstrated that use of filters, centrifuges, and hydrocyclones makes scale-up difficult and decreases efficiency. Consequently solvent deashing processes such as the Lummus Antisolvent Process [489], the Kerr – McGee Super-critical Solvent Process [490], and the BCL Solvent Deashing Process [491], [492] have been recognized as deashing processes for a pioneer plant because of their ease of scale-up with relatively low capital costs.

The bottoms and solids are fed to partial oxidation and/or a boiler for hydrogen generation and heat recovery, respectively. Hydrogen is a major cost component in coal liquefaction. Usually, hydrogen is produced by the gasification of residual coal products and raw coal or by steam reforming of natural gas. Usually, light hydrocarbon products are used as fuel for fired furnaces in the liquefaction plant. In order to produce distillable liquids, hydrogen is required in the range of 6 – 8 wt % based on dry and ash-free coal.

3.9. Commercial Processes

Significant advances have been made in liquefaction processes since the 1940s. Milder operating conditions have been achieved, distillate yields have been increased, and efficiency of hydrogen utilization has been improved. Notable developments are the recycle of heavy liquids, the adoption of multistage processing, and the recognition that selective catalysts are required in all reaction stages.

3.9.1. Kohleoel (Ruhrkohle-Veba Oel) Process

In Germany, the first oil crisis initiated a revival of coal to oil technologies which had been in industrial-scale application in the early 1940s. National energy planner recognized the need for intensified conversion efforts, so that four companies got involved in three development projects all based on the old German IG Farben Technology:

Ruhrkohle AG (RAG, RUR)/Veba Oel AG
Saarbergwerke AG
Rheinische Braunkohlenwerke AG (Rheinbraun)

Proof of concept tests was carried out using process development units (PDU) at a scale of 0.1 – 0.2 t/d, and two pilot plants (PP) were built to demonstrate the technology, one designed for 200 t/d (RAG/Veba Oel) at Bottrop and another for 6 t/d (Saarberg). In 1986, the 6 t/d pilot plant and PDU of Rheinbraun were closed down. The 200 t/d PP was operated from 1981 to 1987, producing over 85 000 t of distillate products from 170 000 t of coal over approximately 22 000 operating hours [24]. In May 1987, RAG/Veba Oel successfully completed their 200 t/d PP test runs to modify the hydrogenation of vacuum residue from crude refining. Coal-based tests were continued in a PDU by RUR and Deutsche Montan-Technologie (DMT) to support the Bottrop PP during its test runs and also for process optimization until 1995. In 1997, the PDU was restarted to support the work for a feasibility study of

5000 t/d demonstration plant targeting the liquefaction of Xianfeng lignite in Yunnan province, China.

Therefore, the Kohleoel process with Integrated Gross Oil Refining (IGOR$^+$) (see Fig. 32) is a relatively recent development. This process aims to obtain "straight-run" fuels finished directly. Coal is mixed with a recycle solvent and relatively low-active iron catalyst (red mud) before the slurry is hydrogenated at elevated pressure and temperature, typically at 30 MPa and 470 °C. The specific coal feed rate to an upflow tubular reactor (c) is in the range 0.5 – 0.6 t m^{-3}h^{-1}. The reactor effluent is passed to a hot separator (d) and products remaining in the gas phase are hydrotreated in fixed-bed reactors (f) at 350 – 420 °C under the same pressure as in the main reactor. The hydrotreated products are depressurized and cooled. The liquid products from the first of these stages are recycled to the slurry-making step as part of the solvent. The liquid product from the second stage is routed to an atmospheric distillation column, yielding a light oil (C_5 – 200 °C) and a middle oil (200 – 350 °C) product. The bottoms from the hot separator pass to a vacuum column (e) to recover distillable products. These products are added to the hydrotreating reactor feed, and are subsequently largely recycled as solvent. The vacuum column bottoms, consisting of pitch, mineral matter, unreacted coal, and waste catalyst, would be used as a gasifier feedstock for hydrogen generation if the process were in a commercial stage. Process yields and quality [24], using German bituminous coal (Prosper coal), are summarized in Tables 27 and 28.

Table 27. Product yields of Kohleoel process

Product	Yield
Gaseous hydrocarbons (C_1 – C_4)	19.0
Light oil (C_5 – 200 °C)	25.3
Middle oil (200 – 325 °C)	32.6
Unreacted coal and pitch	22.1

Table 28. Kohleoel process – product quality obtained with Prosper coal

Nitrogen, ppm	39	174
Oxygen, ppm	153	84
Sulfur, ppm	12	< 5
Density, kg/m^3	772	912

3.9.2. NEDOL Process

In 1983, New Energy and Industrial Technology Development Organization (NEDO) of Japan has developed a new process concept (NEDOL process) integrating the advantages of three different bituminous coal liquefaction processes (see Table 29) to produce liquid fuels for the transportation sector.

Table 29. Bituminous coal liquefaction processes developed between 1978 and 1983 in Japan

Process	Developer	Unit scale
Direct Coal Liquefaction	Nippon Kokan	2.4 t/d
Hydrogen Donor Process	Sumitomo Metals Industries	1 t/d
Solvolysis Process	Mitsubishi Heavy Industries	0.1 t/d

The NEDOL process was developed through the 1 t/d PSU operation at Kimitsu in 1989 – 1998, and a 150 t/d pilot-plant operation at Kashima in 1996 – 1998. In the pilot plant tests, seven runs were carried out using three types of coal of different rank (Tanito Harum and Adaro coals from Indonesia and Ikeshima coal from Japan) which were liquefied without serious problems. A 80 days continuous coal liquefaction operation was achieved successfully during these test runs [44],[47],[493], obtaining 58 wt % daf oil yield, with high coal concentration (50 wt %) in the slurry.

CCRI of China, NEDO, and Centre for Coal Utilization of Japan (CCUJ) signed an agreement to carry out a feasibility study for a 5000 t/d demonstration plant in Heilongjiang province using Yilan coal. Process evaluation, environmental impact assessment and economic analysis was carried out from 1997 to 1998.

The NEDOL process is a single-stage dispersed catalytic liquefaction process as shown in Figure 33. The distillate recycle solvent is hydrogenated catalytically in external fixed bed reactors to increase the concentration of H-donor compounds. Bituminous and subbituminous coals are slurried with the H-donor solvent and iron-based catalyst (a) to be hydrogenated at 450 – 465 °C and 17 – 19 MPa. The nominal slurry residence time in simple upflow tubular reactors (c) is 60 min while the actual slurry phase residence times varies between 90

Figure 32. Schematic diagram of the IGOR$^+$ coal liquefaction process

and 180 min depending on the gas : slurry feed ratio in the reactors. The products are cooled, depressurized and separated by atmospheric (d) and vacuum distillation columns (e). Part of the middle distillate and all of the heavy distillate are recycled as solvent via the hydrogenation step. The vacuum column bottoms, which contain unreacted coal, mineral matter, and catalyst are withdrawn from the process for production of hydrogen. In this process, no bottoms are recycled (one-through operation) to simplify the process. Since the organic matter in the bottom withdrawn with the solids represents a substantial loss of potential products, the process is limited to coal of relatively low ash content.

The middle and heavy distillates from the vacuum column are fed to solvent hydrogenation reactors (g) which are of the trickle-flow fixed-bed type, operating at 320 – 400 °C and 10 – 15 MPa. The catalysts used are variants of those used in the conventional petroleum industry for hydrodesulfurization of crude oils. The reactor products are depressurized and fed to a flash stripper (f) where the hydrotreated naphtha is removed. The main stream from the flash stripper is recycled to the coal slurry making step as the solvent. Typical operation results of a 150 t/d pilot plant using Tanito Harum Indonesian subbituminous coal are summarized in Tables 30, 31, 32 [23], [44].

Table 30. NEDOL process conditions with Tanito Harum coal

Reaction temperature	460 °C
Reaction pressure	17 MPa
Coal in slurry	50 wt %

Density, kg/m^3	857	978

3.9.3. Solvent-Refined Coal (SRC-I and SRC-II) Processes

Interest in producing a substitute fuel for electric utility boilers led the Southern Company and Electric Power Research Institute to explore the Solvent Refined Coal (SRC-I) process. This is a

Figure 33. Schematic diagram of the NEDOL process
a) Slurry mix tank; b) Slurry heater; c) Liquefaction reactor; d) Separator; e) Atmospheric distillation column; f) Stripper; g) Catalytic solvent hydrogenation; h) Vacuum distillation column

one-stage thermal reaction process in which coal is solubilized (at ca. 450 °C and 10 – 14 MPa for 30 – 60 min) in a recycle solvent, and deashed to remove mineral matter, producing an ash-free reduced-sulfur solid fuel. The 6 t/d pilot plant operation of SRC-I, which started in 1974 at Wilsonville, Alabama, USA, was initially unsuccessful, because of problems of solvent imbalance and degeneration of solvent quality with successive recycling [243], [244]. An ebullated-bed catalytic hydrotreater at the SRC-I plant provided additional flexibility in solvent balance and in maintaining the quality of the recycle solvent.

At Fort Lewis, Washington, USA, the process was modified to SRC-II by Gulf Oil Company and others in a 50 t/d pilot plant in 1977 to produce liquid fuels (see Fig. 34). In this process, coal is hydrogenated in a single-stage reactor (c) without catalyst, but the distillation bottoms are recycled to take advantage of the catalytic activity of the coal mineral matter. Bottoms recycle also provides another important function: it allows residue to be selectively cracked to distillate without excessive production of gaseous hydrocarbons. For this reason, this recycle is an integral part of essentially all processes designed to produce a distillate product. In the normal SRC-II mode, most low-rank coals gave low yields and caused operability problems, because of the high product viscosity. The use of dispersed catalysts could overcome these difficulties [494]. The further development of SRC-I and SRC-II has moved away from the original aim of refining coal in favor of distillate production. The Wilsonville plant continued to be funded by the DOE until 1992 as a pilot-scale test facility for the whole US direct liquefaction development program. The SRC processes have now been abandoned in their original form, but elements have been incorporated in the more recent US processes.

3.9.4. Exxon Donor Solvent Process

Exxon started the development of the Exxon Donor Solvent (EDS) process in the 1970s, the 250 t/d pilot plant started operation at Baytown, Texas, in 1980. The pilot plant was operated until 1982, further research continued until at least 1985. At this point, Exxon considered that the process was ready for commercialization.

Figure 34. Schematic diagram of the SRC-II process
a) Slurry mix tank; b) Slurry heater; c) Reactor; d) Separator; e) Atmospheric distillation; f) Vacuum distillation; g) Gas purification

The EDS process is a single-stage noncatalytic liquefaction process (see Fig. 35). The distillate recycle solvent is hydrogenated catalytically in an external fixed bed reactor to increase the concentration of H-donor compounds. In its original version, coal is slurried with the H-donor solvent (200 – 425 °C) and hydrogenated at 425 – 450 °C and 10.3 – 17.2 MPa in a plug-flow tubular reactor (c). The reactor effluent passes to gas – liquid separators (d), from which the liquid product is fed to a vacuum distillation column (e). All of the naphtha and part of the middle distillates are recovered as products. The rest of the middle distillate is recombined with the heavy distillate to form the recycle solvent. The vacuum distillation column bottoms, containing the solid, are fed to a flexicoker unit for producing additional liquids and fuel gases. The coke is gasified to produce hydrogen, supplemented, if necessary, by gasification of raw coal or steam reforming of the light hydrocarbon gases.

Hydrogenation of the recycle solvent is carried out in a fixed-bed catalytic reactor (f), using conventional refinery catalysts for hydrodesulfurization. The reactor is operated in the region of 370 °C/11 MPa, although conditions are varied to control the degree of hydrogenation of the solvent and thus maintain its quality.

In a later development, a bottoms recycle operation was added to the EDS feed to provide additional residence time for conversion, and perhaps to utilize the catalytic activity of the mineral matter. This feature has been taken over from processes such as the CONSOL CSF process and the British Coal LSE process. These processes have in common that the primary coal liquefaction takes place in the absence of any added catalyst, ostensibly to avoid the rapid deactivation of the catalyst that is presumed to occur in the presence of the coal mineral matter. Distillate yields in the 250 t/d PP were lower than in the smaller test facilities because the high gas holdup in the reactor – probably a result of the high slenderness ratio of the reactor – led to a reduced residence time [19], [495], [496].

3.9.5. H-Coal Process

The H-Coal process is a catalytic single-stage liquefaction process (see Fig. 36) developed by Hydrocarbon Research Incorporated (HRI, now Hydrocarbon Technologies Incorporated, HTI) as an outgrowth of their H-Oil process for upgrading heavy oils. The process was successfully scaled up from 3 t/d to a 200 t/d pilot plant (600 t/d in the fuel oil mode) at Catletts-

Figure 35. Schematic diagram of the EDS process
a) Slurry mix tank; b) Slurry heater; c) Plug-flow reactor; d) Separator; e) Vacuum distillation; f) Catalytic solvent hydrogenation; g) Atmospheric distillation

burg, Kentucky, from 1980 to 1983. At high coal throughput (fuel mode), a low-sulfur fuel oil was produced. Separating solids from heavy liquid products in the fuel oil mode was difficult. At reduced throughput (syncrude mode), the product was an all-distillate "syncrude". In this mode, the solids were separated by vacuum distillation. The distillation bottoms could be used for hydrogen production via gasification. Over the two years period, the plant proved capable of prolonged continuous operation, however, the aim of its commercialization has been abandoned. The H-Coal process remained the basis of most subsequent process development sponsored by the US DOE and was effectively incorporated into the Catalytic Two-Stage Liquefaction (CTSL) process [19], [28], [497], [498].

A key feature is the novel reactor design (see Fig. 37) with an ebullated bed of conventional supported hydrocracking catalysts. Coal, recycle solvents, that contain unreacted coal solids, and hydrogen gas are heated and fed to the reactor to contact the catalyst at temperatures of 425 – 455 °C and a pressure of 20 MPa. The catalyst particles, which are in form of 1.5 mm extrudates, are fluidized by the upward flow of internally recycled reactants. In the expanded bed, reactants flow over the weir to the inlet of the ebullating pump. The catalyst particles are too dense to enter the pump or to leave with the effluent, although fines undoubtedly permeate the whole system. Spent catalyst is periodically withdrawn and replaced with fresh catalyst to maintain a constant level of activity. The ebullated bed design promotes gas – liquid – solid contact, facilitates isothermal operation, and allows solids, which could plug a fixed-bed system, to pass through the reactor. The reactor products pass to a flash separator. Liquids in the gas – vapor stream are condensed and routed to an atmospheric distillation column, separating naphtha and distillate products. The flash bottoms are fed to a bank of hydrocyclones. The overhead stream, which contains 1 – 2 % solid, is recycled as a part of solvent. The underflow is routed to a vacuum distillation column. Solids are removed with the vacuum bottoms, while the vacuum distillate forms a part of the products.

3.9.6. Catalytic Two-Stage Process

The CTSL process is a development of the H-Coal single-stage process. The process was further developed over a period of almost 15 years in the pilot plant at Wilsonville. This plant closed in 1992, but development work has been continued by bench-scale and PDU testing at HTI's Lawrenceville facilities under support of the US DOE. The CTSL process has now evolved into a generic composite of much of the liquefaction development work funded by the DOE in the 1980s and 1990s. A closed-coupled configuration has been adopted in which both stages use an active supported catalyst. In more recent work, HTI has included an in-line hydrotreater after the second-stage reactor to improve the product qualities.

One problem with the single catalytic stage is that hydrogenation reactions are best carried out at relatively low temperatures where the equilibrium is more favorable, but conversion reactions are faster at higher temperature. To overcome this, research was conducted on the use of multiple reaction stages. In the Lummus/Cities Service bench unit, the coal was converted to a soluble form in the first stage at relatively high temperature but short contact time. The first stage product was deashed, and converted to distillate liquids at around 400 °C in an ebullated bed LC-Finer unit. A similar configuration was installed at the Wilsonville plant, which employed a Kerr – McGee Critical Solvent Deasher between a thermal first stage and an ebullated-bed second stage supplied by HRI. It was recognized that the location of the deashing unit between the two stages had little effect on catalyst life. The most important factor in initial catalyst deactivation was deposition of carbonaceous material, not poisoning by metals in the mineral matter [441–443]. This led to "close coupling" of the two reactor stages, with deashing applied to the second-stage product. By concentrating solids in the recycle stream, the amount of material processed by the deasher was significantly reduced, and the unconverted coal was given additional residence time.

The Wilsonville unit was subsequently used to explore a variety of staged reactor configurations, including two ebullated-bed catalyst stages, the use of a dispersed iron oxide as a first-stage catalyst, and alternative temperature staging. This resulted in substantial reductions in production of gaseous hydrocarbons and residues, with a corresponding increase in distillate liquids [340], [341]. Subsequent works supported by the DOE investigated the use of dispersed catalysts based on iron, molybdenum, and other metals [335–337].

Figure 37. H-coal ebullated bed reactor [497]

In a collaborative project, CONSOL, the University of Kentucky, LDP Associates, HTI, and Sandia National laboratories have been exploring several advanced concepts for improving direct liquefaction process economics. A schematic diagram of the process [36] is shown in Figure 38.

3.9.7. HTI Coal Process

HTI chose a proprietary dispersed superfine, iron catalyst instead of the supported catalysts in the closed-coupled two-stage liquefaction reactor configuration [22], [482]. The latest process is called HTI Coal Process. In 1997, HTI signed a two-year agreement with Shenhau Clean Coal Technology Development (SCCT) and CCRI to execute a feasibility study for a direct coal liquefaction plant using Shenhau coal. The project is to build a mine-mouth liquefaction plant of 12 000 t/d capacity using coals produced in the Shenhua coalfield in Northern Shaanxi Province and Inner Mongolia near Baotou city [22].

The HTI Coal Process (see Fig. 39) consists primarily of two backmixing reactor stages utilizing a iron catalyst (GelCat) plus a fixed-bed in-line hydrotreater. The process operates at a pressure of 17 MPa and reactor temperatures in the range of 400 – 460 °C. A slurry consisting of pulverized coal, recycle solvent, and recycled residue is mixed and pressurized through a fired preheater (b) and passed along with hydrogen and catalyst into the first-stage reactor (d). The effluent from the first reactor is separated in an interstage separator (e) to remove gases and hydrocarbon vapors, the slurry is sent to the higher temperature second-stage reactor (f). Effluent from the second-stage reactor is flashed and the overhead gas – vapor stream is fed to the in-line hydrotreater (h) together with the overheads from the interstage separator for enhanced upgrading to clean fuels. A part of the atmospheric bottoms stream, containing solids, is used as recycle with a portion going to a vacuum distillation column (j). A typical operation result of the continuous flow unit (30 – 50 kg/d) using Shenhau coal [22] is summarized in Tables 33 and 34.

Table 33. HTI Coal process yield (wt % daf) with Shenhau coal

Coal conversion	90 – 93
Distillate (C_5 – 524 °C)	52 – 68
Residue (524 °C)	7 – 22

Table 34. HTI Coal product quality with Shenhau coal

Product quality	Whole distillate
Carbon, wt %	87.6
Hydrogen, wt %	12.7
Nitrogen, wt %	0.14
Sulfur, wt %	0.10
API gravity	857

3.9.8. BCL Process

The Brown Coal Liquefaction (BCL) process is a two-stage liquefaction process developed by Nippon Brown Coal Liquefaction (NBCL) through the 50 t/d pilot plant operation at Morwell, Victoria, Australia. The pilot plant was operated over the period 1985 – 1990 under full support of NEDO, processing in total 70 000 t of coal. The process is designed specifically to handle very low-rank coals such as those found

Figure 38. Schematic diagram of the CTSL process

in the Latrobe Valley of Victoria, which contain more than 60 % of moisture. This process consists of slurry dewatering, primary hydrogenation, solvent deashing, and secondary hydrogenation process units. Raw brown coal is slurried by adding a fine iron catalyst and recycle solvent which includes some bottoms from primary and secondary hydrogenation. The moisture content in the raw brown coal is removed by heating the slurry. The slurry is transferred through a fired preheater along with hydrogen into liquefaction reactors which are maintained at 430 – 460 °C and 15 – 20 MPa. Effluent from the reactor is cooled, depressurized and separated. The bottom product ($bp \geq 420$ °C) is deashed and fed into the secondary hydrogen-

ation unit to be hydrogenated further to produce light oil and hydrogenated heavy solvent. In 1993, NBCL completed the pilot plant program, and attained all the developmental objectives: 52 wt % oils yield, 1700 h continuous operation, 700 ppm ash concentration in the bottom at the outlet of the deashing unit, development of a secondary hydrogenation catalyst, and establishment of a more economical slurry dewatering method [46].

Following extensive pilot plant operation, R&D using a 0.1 t/d bench scale unit and related equipment was continued from 1994 until 1997 at Takasago, Japan to improve the reliability, economics, and environmental compatibility of the process. Based on the R&D results, an Improved BCL Process was proposed [46]. The Improved BCL Process is a modification of the BCL Process and a single-stage liquefaction method as shown in Figure 40. This process consists of the four operations slurry dewatering, liquefaction, in-line hydrotreating, and solvent deashing. The Improved BCL Process is a simplified liquefaction process with the following advantages: high efficiency and low investment, use of a highly active and inexpensive iron catalyst such as limonite ore pulverized with process solvent, improved quality of recycle solvent and product oils by the in-line hydrotreater. The deashed bottoms recycling operation achieves a high oil yield with mitigation of erosion problems.

Compared with the results of the pilot plant, in the bench-scale unit oil yield could be increased, product quality improved, and scale formation in the reactors suppressed using 1 wt % catalyst or less. It was estimated that the improved BCL Process could decrease the crude oil equivalent price by 24 % compared with the BCL Process at the Australia pilot plant. Typical test run results using Victorian brown coal and Indonesian low-rank coal are shown in Tables 35, 36, 37.

Table 35. BCL process conditions

	BCL	Improved BCL
Coal used	Yalloum	Banko
Tested by	50 t/d	0.1 t/d
Reaction pressure, MPa	15	15
Reaction temperature, °C	450	450

In 1999, NEDO and BPPT (Agency for the Assessment and Application of Technology) of Indonesia signed an agreement to carry out a feasibility study for a 30 000 t/d direct coal liquefaction plant in Tanjung Enim, South Sumatra using Banko coal (lignite). Conceptual design, environmental impact assessment and economic analysis will be carried out until 2002 [26].

3.9.9. Liquefaction Solvent Extraction Process

The Liquefaction Solvent Extraction (LSE) process was developed by British Coal Corporation between 1973 and 1995 using a 2.5 t/d pilot plant at Point of Ayr, North Wales. After the operation of the pilot plant, an outline design for a 65 t/d demonstration plant has been developed, however, currently there are no plans to construct the plant. Figure 41 shows a schematic flow diagram of the process. Coal is slurried with a process-derived recycle solvent, preheated, and fed to an noncatalytic digestion step, which consists of two or more continuous-stirred tank reactors in series. These reactors are operated at 410 – 440 °C and 1 – 2 MPa, the pressure required solely to reduce solvent vaporization. No hydrogen is used in this step, but the solvent acts as a hydrogen donor, transferring up to 2 wt % of

Figure 40. Schematic diagram of the Improved BCL process

hydrogen to the coal [499]. The digester product is partially cooled and filtered in a vertical-leaf pressure filter to remove solids. The filter cake is washed with a light recycle oil fraction to recover product and dried under vacuum. In commercial operation the filter cake would be gasified to produce hydrogen. The filtered coal extract passes to a distillation column to recover the light oil wash solvent and is then preheated, mixed with hydrogen, and routed to two ebullated-bed reactors in series in which the coal extract is hydrocracked at 400 – 440 °C and up to 20 MPa. The reactor effluent is cooled, depressurized and fed to a atmospheric distillation column to recover distillate products. The cut-point of this column is adjusted to maintain solvent balance, resulting in a product that typically boils below 300 °C. The column bottoms are routed partially to a vacuum distillation column, used to control the level of pitch in the recycle solvent. The overheads from the vacuum distillation column are recombined with the main atmospheric column bottoms stream and recycled as solvent to the slurrying step.

The pilot plant operating program concluded with a steady-state demonstration run. The results from this run indicate that it would be possible to operate the process in an all-distillate product mode, removing the requirement for a vacuum column. Solvent quality was maintained without the need for a separate, thermal cracking step. Primary product quality data are shown in Tables 38, 39, 40. The total distillate product yield is in the range of 60 – 65 wt % on dafc [50].

Table 38. LSE process conditions

Solvent : coal ratio, wt/wt	2.2
Digestion pressure, MPa	1.5
Digestion temperature, °C	431
Nominal residence time, min	50

Sulfur, wt %	0.04

3.10. Environmental Considerations

Direct and indirect coal liquefaction create similar environmental concerns, although the former produces more aromatic liquids [500]. The toxicity and carcinogenicity of coal products are largely due to polycyclic aromatic hydrocarbons (PAH) and their nitrogen-containing analogues (N-PAC), which are found in fractions boiling at ca. 370 °C or higher [501].

Carcinogens and mutagens are removed by denitrogenation, hydrogenation, and hydrocracking. In processes where the higher boiling products are catalytically refined or recycled to extinction, mutagenic activity may be substantially eliminated [501], [502]. Refined coal and shale products are generally equivalent, in terms of potential health hazard, to their petroleum derived equivalents [503].

Preferably, high-boiling, coal-derived liquids should not be stored, but fed directly to a gasifier, if this is their intended disposition.

Health hazards from intermittent contact with refined coal liquids appear to be negligible. The main danger does not confront the general public, but the plant operators. Strong precautionary practices should be instituted in the direct area of process operation.

The liquefaction technologies have advanced significantly since the mid-1980s, which has produced great benefit not only for improving economics but also for environmental adaptation. The liquefaction plants to produce coal-derived fuels will be designed to meet the highest standards for environmental compliance. The transportation fuels produced by advanced coal liquefaction technologies will be environmentally superior to their petroleum-derived counterparts and will be capable of meeting all requirements of clean air standards and regulations in major countries.

3.11. Economic Aspects

In 1985, oil price fell suddenly and had remained low until spring 1999. Therefore, interest in coal liquefaction for the production of transportation fuels has declined except in a few countries. China and Indonesia are now executing collaborative feasibility studies on direct coal liquefaction plants. It remains to be seen whether a future increase in oil prices will result in renewed interest and possibly in full-scale commercialization of these plants. Because of resource limitation of

conventional petroleum caused by rapid rate of economic growth particularly in the Pacific rim, there will be a worldwide shortfall in petroleum liquids in the 2025 – 2030 timeframe [504]. This shortfall will impact all countries by constraining their ability to maintain their share of imports, and as a result, the world is likely to experience a liquid fuels shortfall anytime between 2005 and 2030. The liquefaction technologies must be in the state of readiness for commercial deployment about 15 years earlier, because lead times for the introduction of new energy technologies are on the order of 10 to 15 years, even after technologies are technically ready for commercial deployment.

Although direct liquefaction technology has undergone very significant improvements in the 1990s and achieved a high level of technical readiness, liquefaction products are still not cost competitive against crude oils, with prices being in the range of $ 10 – 20/bbl over the last decade. Continuing R&D is, therefore, needed to reduce costs to meet the target of 2015 for the start of commercial deployment. The US DOE contracted with Bechtel to develop a conceptual commercial design to produce hydrotreated liquid products from either bituminous or subbituminous coal [10]. The Bechtel design yielded a cost of about $34/bbl of crude oil equivalent (COE). This cost is significantly lower than earlier estimates of $ 40 – 50/bbl because of process improvements from R&D undertaken over the last decade. Because direct liquefaction technology is still evolving and additional process improvements are expected, costs will decrease further as improvements are incorporated. Areas of most importance in reducing costs include decreasing capital investment, improving product yields, and lowering catalyst cost.

The key to commercialization will be integration with the existing petroleum refining/distribution infrastructure. In achieving commercialization, two intermediate technologies are important. The first is co-processing of petroleum-derived wastes (plastics, tires, waste oil) with coal. Developing this technology is being driven by dwindling landfill availability and increase in tipping fees. The second technology is coprocessing of coal with heavy petroleum residues or oils. This option is likely to account for the first production of coal-base transportation fuels in existing petroleum refineries.

1. Introduction

Coal pyrolysis is the heating of coal to produce gases, liquids, and a solid residue (char or coke). Pyrolysis occurs in all coal utilization processes, i.e., combustion, gasification, liquefaction, and carbonization. The nature of pyrolysis and of the products is intimately related to the operating conditions and to the composition and properties of the coal. Consequently, control of pyrolysis is important in coal utilization processes.

The thermal decomposition (or devolatilization) of coal is illustrated using Wiser's model of coal structure (see Fig. 1) [1]. This model, one of many in the literature, represents the types of structures found in coals. Although it does not necessarily depict the structure of a particular coal, it is consistent with knowledge of coal physics and chemistry.

Pyrolytic rupture of functional groups attached to aromatic and hydroaromatic units of the coal structure leads to the formation of gases

Figure 1. WISER's model of coal structure [1]

(CO, CO_2, H_2O, CH_4, C_2H_4, etc.). In addition the cross-links (indicated by arrows in Fig. 1) break and release reactive free radicals (fragments). The fate of these radicals controls the overall yield and distribution of products. Stabilization of the fragments with hydrogen gives primary volatile products and favors a high yield of gases and liquids (see Fig. 2). Some primary products are also obtained by release of low molecular mass species (the so-called mobile phase), which are believed to be trapped within the coal network [2]. However, if the fragments undergo secondary cracking, polymerization, or condensation reactions, part of the primary product is converted to char.

The four fundamental aspects of this complex process are the following:

1) The thermoplastic behavior of some coals (Chap. 2),
2) The yield and distribution of pyrolysis products (Chap. 3),
3) The temperature and time dependency (kinetics) of the pyrolysis process (Chap. 4), and
4) The source of hydrogen for the stabilization of reactive fragments (Chap. 5).

2. Thermoplastic Properties of Coal

When bituminous coal is heated, it undergoes marked chemical and physical changes, which are influenced by rank, petrographic composition, particle size, heating rate, temperature, and the atmosphere in which pyrolysis occurs. Bituminous coal softens and melts at 350 – 400 °C. In contrast, lignite, subbituminous coal, and anthracite do not soften when heated. Fusion and agglomeration may produce a fluid mass. Concurrently, thermal decomposition may liberate gases and vapors, producing a foamlike material with significant volume change. At some point, the foam solidifies.

These macroscopic changes are accompanied by microstructural rearrangements within the fluid phase, which govern the properties of the resulting coke. Development of the coke microstructure often involves formation of an intermediate phase called carbonaceous mesophase (see Section 2.4).

Volume changes (expansion and contraction) occur in some bituminous coals on heating. Initial softening at temperature T_s produces a fluid. As softening increases, pores and voids are eliminated and the material undergoes volume contraction, reaching a minimum V^c at temperature T^c. At this point, rapid gas evolution leads to expansion, producing a maximum V_s at temperature T_e. With a further increase in temperature, the fluid coal resolidifies at temperature T_r; the corresponding volume is V_r. These phenomena, i.e., softening, swelling, and resolidification are collectively referred to as the *thermoplastic*

properties of a coal, otherwise called the softening, plastic, fluid, agglomerating, caking, and coking properties of coal.

The terms "caking" and "coking" are sometimes used incorrectly as synonyms. In a strict sense, *caking* describes softening and agglomeration of coal on heating, without any implications about the nature of the resulting solid. *Coking coals,* on the other hand, are those that form strong, coherent solids (metallurgical cokes) on softening and resolidifying in conventional coke ovens. In other words, all coking coals exhibit caking behavior, but not all caking coals can be coked. Coal that does not become fluid when heated is generally termed nonswelling or noncaking.

Figure 2. Primary and secondary reactions in coal pyrolysis

Continued heating of a *semicoke,* i.e., a solid residue still containing appreciable volatile matter, to ca. 1000 °C leads to further decomposition with formation of a solid residue termed *coke.* Coke contains little or no volatile matter and undergoes little further volume change when heated. The volume changes occurring during the transformation of a coal into a semicoke depend on the fluidity of the plastic mass and its resistance to the escape of gases and vapors.

An understanding of the thermoplastic behavior of coal is important for nearly all coal conversion and coke-making processes. For example, plasticity development and agglomeration may create severe operating difficulties in gasifiers.

In a *moving-bed gasifier*, as the coal proceeds down the (sometimes pressurized) reactor, it devolatilizes at relatively low heating rates (25 – 65 °C/min) in the presence of a reducing atmosphere. Under these conditions, bituminous coal undergoes, in varying degrees, thermoplastic transformations that can lead to the formation of coke masses. These are detrimental to the flow of gases and solids, resulting in poor operation of the gasifier. In the extreme, coke agglomerates can completely plug the reactor.

In a *fluidized-bed gasifier*, an agglomerated mass may disrupt the fluidization. As a complicating factor, highly swollen coke may greatly reduce the bed density and lower the throughput. As a further complication, a highly swollen coke mass tends to disintegrate when it is fluidized, producing excessive fines that are carried from the bed and must be separated from the exhaust gas.

In contrast to the general objectives in gasification and combustion, extensive plasticity development is essential during carbonization to produce metallurgical coke. The main objective of the coking industry is to produce coke for blast furnace operation. In this context, research focused on the identification of coke microconstituents and the mechanism of their formation. The improvement of coke microstructure depends largely on the ability to modify the thermoplastic properties of the coal feedstocks and the associated mesophase. This is of particular significance because of the interest in the plastic behavior of weakly caking coal as a supplement to the reserves of prime coking coal.

2.1. Experimental Techniques

The industrial importance of the thermoplastic properties of coal is reflected in the many methods available for its characterization [3]. A common objective of these techniques is to predict the behavior of coal in various processes.

The *free-swelling index* (Gray – King) provides a visual comparison of cokes carbonized under well-defined conditions. The method is inexpensive, rapid, and reproducible, but lacks flexibility. *Hot-stage optical microscopy* permits the visual observation of morphological changes caused by heat. The *Foxwell gas flow method*

measures the resistance to the flow of a highly purified gas through a bed of coal during continuous heating; the pressure drop indirectly measures the fluidity of the plastic mass. The *constant torque plastometer* records the velocity, as a function of temperature, of a rotating shaft passing through a bed of coal. In the variable torque plastometer, the velocity is kept constant and the required torque measured as a function of temperature. The resulting measurements of fluidity provide a sensitive index of oxidation or weathering, but not of swelling. The heating rate is limited to ca. 3 °C/min. In the *dilatometer,* the volume change on solidification is measured as a function of temperature. This is applicable over a wide range of heating rates and provides data on dilation parameters and transition temperatures, but not on fluidity changes.

These empirical tests require that experimental conditions be specified when results are reported. Furthermore, these tests measure different aspects of thermoplastic behavior; therefore, there is no single best method or technique that can predict the changes which occur in all industrial processes. Selection of a test method depends on the utilization process.

2.2. Experimental Variables

The thermoplasticity of a coal is a complicated phenomenon. It is affected by softening and rheological properties and by formation of gas bubbles [7], which are strongly influenced by pyrolysis conditions and feedstocks.

2.2.1. Coal Rank and Petrographic Composition

The thermoplastic properties of coal vary widely as a function of rank. Moreover, the plastic properties of some bituminous coals serve to differentiate them from others of similar rank. A number of attempts have been made to *correlate plastic properties with rank.* Swelling, measured by dilatometry, exhibits a maximum for a volatile-matter content of ca. 25 – 28 wt %; the Gieseler fluidity reaches a maximum at ca. 28 – 32 wt % of volatile matter [5]. Correlation of the free-swelling index (FSI) with the maximum Gieseler fluidity is poor, which is not surprising; rather, it illustrates the heterogeneity of coal [4]. Some variations can be expected because of the obvious differences in test conditions. In the FSI test, a 1-g sample of coal (250 µm particle size or 60 mesh) is heated in a silica crucible at 820 ± 2 °C for 2.5 min; the swelling is compared to that of a standard. The Gieseler fluidity test measures the rotary speed (in dial division per minute, ddpm) of a stirrer under a constant torque in a compacted 5-g charge, heated at 3 ± 0.1 °C/min from 300 °C until it resolidifies. However, the FSI does not increase monotonically with increasing Gieseler fluidity. In any case, the data support the concept of an optimum fluidity that is essential for maximum swelling.

The principal maceral responsible for coal plasticity is *vitrinite,* the predominant petrographic constituent of most United States coals. *Exinite* differs from vitrinite of the same rank by containing more hydrogen and volatile matter. Exinite exhibits a lower softening temperature, wider plastic range, greater Gieseler fluidity, and higher dilatometric swelling than vitrinites (see Fig. 3) [3].

Figure 3. Expansion of vitrinites and exinites [3]

Inertinite is infusible and inert, regardless of coal rank. It is distinguished from vitrinite of the same rank by its higher density and lower hydrogen and volatile matter contents [5].

Plasticity usually reflects the properties of the constituent macerals, but it also depends on the dispersion of exinite and inertinite within the vitrinite. This dispersion determines the degree of interaction between the different macerals. Consequently, predicting the thermoplastic behavior of a coal from its petrographic (maceral) analysis alone is impossible.

2.2.2. Heating Rate

The thermoplasticity of coals increases as the heating rate is increased [6]. Shock heating rates (above 100 °C/min) significantly increase the maximum swelling [6]. However, beyond a limiting heating rate (100 – 300 °C/min) a further increase does not increase swelling. On the other hand, at a low heating rate (below 3 °C/min), even a highly plastic coal may not soften or swell.

Figure 4. Effect of heating rate on the characteristic temperatures of a low-volatile bituminous coal (particle size: – 74 µm; pressure: 101.3 kPa of He) [4]
○ Softening temperature; △ Temperature of maximum devolatilization; ◇ Temperature of maximum fluidity [7]; □ Temperature of maximum swelling (dilatometry)

The effect of heating rate can be explained in terms of a competition between evolution of volatile matter and thermal decomposition. At a higher heating rate, reactive components of the volatile matter, which would otherwise be lost before plasticity develops, can participate in secondary reactions that promote fluidity.

With an increase in heating rate, the characteristic temperatures (for softening, maximum swelling, and maximum fluidity) increase, as measured by plastometry or dilatometry (see Fig. 4). Because these temperatures do not shift to the same extent, the temperature range over which the coal is plastic is generally widened.

An important effect of heating rate on the thermoplastic properties of coals is related to the maximum rate of devolatilization [3]. As the heating rate increases from ca. 1 to ca. 7 °C/min, the maximum swelling, maximum Gieseler fluidity, and maximum devolatilization rate all increase [4]. An increase in the heating rate produces a linear increase in the maximum rate of devolatilization. In addition, the maximum swelling increases with increasing heating rate, although this parameter is dependent on particle size. The maximum rate of devolatilization is slightly lower for the larger fraction.

The sequence of events occurring during coal pyrolysis is a function of heating rate. Softening is preceded by a rapid increase in evolution of volatile matter. Within the same temperature range, the viscosity of the sample reaches a minimum [7]. In response to this rapid rise in formation of volatile substances the coal particles and coal bed expand, producing the maximum swelling, determined by dilatometry, and the maximum rate of devolatilization, determined by thermogravimetric analysis [4].

2.2.3. Particle Size

The effect of particle-size variations on the thermoplastic properties of coal has not been widely reported. The data published before 1980 conflict. A few investigations have suggested that extremely fine grinding of the coal particles reduces thermoplastic properties. However, these results are possibly due to increased ease of weathering and oxidation of the more finely ground coal, or to maceral and mineral segregation that occurs during grinding.

Experimental data on particle size must be interpreted with caution. Studies conducted in a Hoffmann dilatometer, which accommodates coarse samples, have shown that the effect of particle size varies according to coal type and petrographic constitutents [5].

The effect of particle size is dependent on heating rate [4]. At a high rate (60 °C/min), a considerable decrease in the particle size resulted in a significant increase in swelling. This confirmed earlier findings that, at a higher heating rate, the maximum swelling was greatest for the smallest size fraction [8], [9]. The behavior at 60 °C/min has been explained as follows:

the smaller coal particles, with their greater surface : volume ratio, fuse more easily with the neighboring particles and produce a homogeneous mixed phase [4]. In contrast, the larger coal particles tend to maintain their individuality [4], [6].

With slower heating (5 °C/min), the swelling parameter for the smaller fraction (– 74 µm) was less than that at 60 °C/min. This was attributed to slower devolatilization at 5 °C/min, resulting in a lower swelling pressure, i.e., the pressure generated inside the particles. In addition, the diffusion distance (the distance traveled by the volatile substances before escaping) is shorter for smaller particles. Therefore, an increase in particle size with slower heating results in greater swelling.

A particle-size effect is also noted in the contraction parameter. In general, the initial contraction of the coal particles is significantly greater for the smallest fraction [4], [8], [9]. This is explained by the suggestion that larger coal particles fuse less than smaller ones because of their lower surface : volume ratios.

2.2.4. Pressure

Until recently, little work had been published on the effects of inert gas pressure on the thermoplastic properties of coal. In the absence of data at elevated pressure, the behavior of coal under typical gasification conditions (elevated pressure and reducing atmosphere) has generally been extrapolated from data obtained at atmospheric pressure. However, this treatment has serious deficiencies.

Several investigations have shown that pressure increases the coke and gas yields at the expense of tar production. This has been attributed to an increased residence time of volatile and plasticizing substances in the coal melt and to a corresponding effect on rheological behavior. Pyrolysis of bituminous coal at elevated pressure has also been shown to increase the Gieseler fluidity (see Fig. 5) [10].

Swelling of coal in dilatometers results from a balance between opposing forces and occurs when the internal (intraparticle or intrabed) gas pressure (swelling pressure) generated in the plastic state is higher than the applied forces that tend to contain it. This internal pressure depends on the coal type, particle size, heating rate, and temperature. Consequently, at elevated pressure, coal swelling depends largely on experimental conditions. For a range of bituminous coals, the rank dependency of the effect of pressure on the maximum swelling parameters was highly variable [4]. In addition, the extent of maximum swelling varied markedly.

Figure 5. Effect of pressure on the Gieseler fluidity of a bituminous coal [10]
∗ DDPM = dial divisions per minute

Other observed effects of pressure, irrespective of coal rank, were an increased contraction parameter and an expanded plastic range. In contrast, with vacuum pyrolysis, maximum swelling, contraction, and plastic range were significantly reduced [4].

The effects of pressure can be explained qualitatively by invoking the concept of optimum fluidity, which is essential for high expansion. If the melted coal is very fluid, swelling is not extensive because the volatile substances escape easily. At the other extreme, minimum fluidity is essential for the material to fuse and entrap volatile material. This implies that an optimum fluidity exists, which is necessary to permit a high degree of swelling. Under vacuum, for example, volatile and plasticizing components are readily removed before sufficient fluidity or swelling

pressure can develop. Hence, thermoplastic behavior is inhibited [4].

Production of volatile matter during pyrolysis is a necessary but insufficient condition for a coal to become plastic and swell. The combined effects of the generated volatile matter and the rheological properties of coal determine thermoplastic behavior [4], [9], [11].

2.2.5. Gaseous Atmosphere

The effects of a gaseous atmosphere on the thermoplastic properties of coal are of interest because in many processes devolatilization occurs in the presence of reactive gases, e.g., H_2, CO/H_2, or CO_2.

The effects of H_2 and He depend on the conditions. However, an increase in the maximum swelling parameter can be correlated with the degree of hydrogenation. At heating rates above 60 °C/min in a high-pressure microdilatometer, the thermoplastic properties of a low-volatile bituminous coal were not significantly different in atmospheres of H_2 or He [4]. The total loss of mass during pyrolysis at ca. 630 °C in these two gases was similar, indicating little hydrogenation at high heating rates.

In contrast, at a low heating rate of 5 °C/min, the maximum swelling is significantly greater at elevated H_2 pressure compared to He. The loss of mass during pyrolysis is also significantly greater in H_2 than in He, indicating some hydrogenation at this heating rate [4].

The maximum Gieseler fluidity (heating rate, 5 °C/min) of a weakly swelling coal (FSI = 0.5) at atmospheric pressure was markedly greater in H_2 than in He or N_2 [10], [12].

2.2.6. Preoxidation

In many processes, thermoplastic behavior of bituminous coals can have undesirable consequences. Caking can be reduced or eliminated by low-temperature (below the softening point) preoxidation, which can destroy thermoplastic properties [5], [6], [13], [14]. In addition, carbonization of preoxidized bituminous coal produces a char with a higher gasification reactivity and surface area than coke produced from untreated coal [15].

Although many studies have been conducted on oxidized or weathered coals, oxidation mechanisms are still poorly understood. Small amounts of oxygen (0.01 – 0.02 wt %) can produce substantial changes in coal plasticity [16]. The first stage of oxidation was postulated as peroxide formation; however, this has not been confirmed experimentally. It was further suggested that the peroxide is unstable above 70 °C and decomposes to yield more stable coal – oxygen complexes with evolution of CO_2, CO, and H_2O.

Another proposed mechanism was that oxidation increases hydroxyl, carboxyl, and carbonyl content [3]. As the temperature rises the hydroxyl groups can condense with the liberation of water:

$$\mathrm{Ar-OH + Ar-OH \longrightarrow Ar-O-Ar + H_2O}$$

where Ar is an aromatic radical.

Fourier transform infrared (FTIR) studies suggest that in the early stages of oxidation, the main functional groups formed are carbonyl and carboxyl [17]. At higher degrees of oxidation, evidence indicates a significant increase in ether, ester, and phenolic groups. Loss of plastic properties on oxidation is attributed to the formation of ether and ester cross-links. The decline in fluid behavior on oxidation can be correlated to a reduction in the aliphatic hydrogen content [18].

The swelling of a highly fluid coal increased on mild oxidation [5], [6], [8]. More severe oxidation sharply reduced swelling.

Little work has been done on carbonization of preoxidized coal under the pressure of a reducing gas. Successful operation of fixed- and fluidized-bed processes depends on the behavior of preoxidized coal when it is devolatilized under these conditions.

A preoxidized coal shows a higher loss of mass during pyrolysis in H_2 than in N_2 [4]. The thermoplastic properties of preoxidized coal are highly dependent on pressure, and maximum swelling increases significantly at an elevated pressure of H_2 or He [4], [19], [20]. This suggests that if preoxidized coal is used as a feed material for a pressurized process, where devolatilization occurs in a reducing atmosphere, the effects of preoxidation are reduced.

Although oxidation is an inexpensive technique for reducing the plastic behavior of coal,

deleterious consequences have been reported [4]. Preoxidation results in an overall loss of carbon (as CO_2) and hydrogen (as H_2O); hence, the heating value is significantly reduced. Consequently, other means of reducing thermoplastic properties are being investigated.

2.2.7. Additives

Inorganic additives are an alternative to preoxidation. They reduce the caking of coal carbonized at atmospheric pressure (see Table 1); however, they have economic and operational drawbacks.

The mechanism of decaking is not known. In general, an additive may function as an inert diluent or in a more active role by chemically interacting with the softened coal. Some inert additives may provide sites for complex reactions of the coal. Some inert additives reduce fluidity by adsorbing primary decomposition products. Removal of 2 – 3 wt % of the extractable bitumen prevents caking completely [5].

Additives may also increase the permeability to gas flow and, therefore, reduce swelling in the coal melt. Compounds like SiO_2, however, serve simply as diluents.

Additives may also react chemically with the pyrolysis products. Substances, such as K_2CO_3, KOH, CaO, Fe_2O_3, Fe_3O_4, HCl, and BF_3, reduce the swelling of coal at atmospheric pressure.

The effectiveness of additives in decaking under gasification conditions has been examined [4], [22], [23]. Compounds of K, Ca, or Fe significantly reduced thermoplasticity under most conditions. Although K_2CO_3 and KOH are effective decaking agents, KCl is not. Similarly, CaO and $Ca(OCOCH_3)_2$ were more effective than $CaCO_3$. Both Fe_2O_3 and Fe_3O_4 destroyed thermoplasticity at 0.1 MPa (H_2 or He), even at ca. 5 wt %.

Effective additives may promote char formation during pyrolysis. Pyrolysis at elevated hydrogen pressure usually increases V_s (see 2). This was attributed to a reduction of char-forming reactions, thereby increasing fluidity of the system [4].

2.3. Development of Thermoplasticity

2.3.1. Softening

Although thermoplastic properties of coal have been studied for many years, softening still lacks a satisfactory explanation. However, a general pattern has been established.

Direct microscopic observations are revealing. Between 325 and 450 °C, depending on coal rank and experimental conditions, visible softening is manifested as follows [6]:

1) Coal particles become mobile and fill the bed space. Larger particles, which soften less than smaller ones, fuse with the smaller particles.
2) So-called fusion pores begin to form as softening continues, depending on particle size and nature of the coal. However, with further softening, the material becomes more homogeneous, making distinction between pores formed by fusion and those formed by devolatilization difficult. As softening continues, viscosity decreases, particle boundaries disappear, and gas evolution increases.
3) With a further increase in temperature, viscosity increases until resolidification occurs, pore volume and vitrinite reflectance increase, and in some cases, anisotropy increases.

Softening can be measured in a dilatometric test by the onset of contraction when a bed of coal is heated under a weighted plunger. A more precise measurement is given by the attainment of a specific degree of fluidity within the plastometer. In all theories of plasticity, it is acknowledged that a fusible material is formed during softening, but differences of opinion exist as to the origin, nature, and function of this material [9].

The homogeneous-melt theory, for example, proposes that coal undergoes pastelike melting throughout the entire mass, but decomposes at the same time, giving rise to gas and an infusible solid [24], [25]; the composition of this mixture depends on time and temperature. Resolidification is observed when the transformation to infusible material is complete. If decomposition proceeds too rapidly before the inception of softening, fusion does not occur and char is formed. On the other hand, if softening occurs before the

evolution of volatiles, a coal fuses and swells to form a coke.

According to the *partial-melt theory,* only a fraction of the coal melts and the remainder is plasticized. The fusible fraction, the coking principle or bitumen, has been identified in benzene and chloroform extracts.

In the *thermobitumen theory,* softening is defined as a consequence of pyrolysis that transforms coal into fluid products. The appearance of these fluid products causes softening and plasticity. Their disappearance by evaporation or thermal decomposition results in resolidification. The fluid products are termed metaplast or thermobitumen, implying that they are the products of pyrolysis.

The *physical and physicochemical theory* proposes that thermal softening is initially a physical process of partial melting of the coal substance to a fluid mass. However, the rheological properties of this mass are subseqently modified by chemical reactions during decomposition. Therefore, development of fluidity is believed to be the result of both physical and physicochemical processes.

In noncaking coal, the decomposition point is lower than the softening point. The rank dependency of these temperatures is illustrated in Figure 6, which shows that plastic coals occupy only a narrow range of rank. Other theories suggest that the fraction of a coal that fuses plasticizes the remainder [26–35].

Thermal softening of coal is apparently not related to physical melting but instead to kinetic phenomena [3], [36]. The development of fluidity may be the result of physical and physicochemical processes without appreciable rupture of covalent bonds during pyrolysis. After melting of the mass, the properties are modified by pyrolytic reactions [31]. This mechanism is consistent with three conditions that have been proposed as being necessary and sufficient for plasticity development [37]:

1) lamellar bridging structures that can be thermally broken
2) a supply of hydroaromatic hydrogen

3) intrinsic ability of micelles and lamellae to become mobile, i.e., ability of the coal to melt independent of thermal bond rupture.

Figure 6. Relationship of volatile matter content to softening points and decomposition points of coals [26]

2.3.2. Swelling

Investigators agree that the softening of coal particles is caused by the melting or solvation of low molecular mass substances or by primary pyrolytic decomposition [5]. Softening causes swelling and the formation and liberation of gas. The gas cannot escape rapidly because of the low permeability of the plastic mass. Hence, gas bubbles are formed with high internal pressures. In response to this internal pressure, the viscous plastic mass swells like baker's dough. The formation of an impermeable plastic mass is a precondition for swelling.

Swelling can be observed in coal particles individually or collectively. *Intraparticle* (single-particle) *swelling* results from the formation of a plastic mass that eliminates the fissures and macropores through which gas could escape. The resulting internal pressure swells the plastic mass. Swelling of particle beds, i.e., *interparticle swelling*, is caused similarly when the plastic mass fills the interparticle spaces, preventing gas from escaping.

The importance of each type of swelling depends on the particle size and the nature of the coal. Intraparticle swelling is only important for weakly coking coal. For coal to form a coherent and strong coke, interparticle swelling is necessary. In highly plastic coal distinction between the two types of swelling is often impossible [22].

The extent of swelling depends on the rate of devolatilization [3], [4]. A minimum fluidity is essential to reduce the permeability of the plastic mass to gas flow and generate swelling pressure. However, if the plastic mass is too fluid, gas bubbles escape at low pressure.

Swelling has been viewed as a process independent of softening [33], [34], [38]. In this light, swelling is a consequence of the pore structure of the starting coal. It is caused by the pressure of the evolved gas trapped within the micropores.

Porosity exhibits a minimum for the higher rank bituminous coals, for which swelling is at a maximum. This mechanism explains intraparticle swelling, but not interparticle swelling. Because microporosity is a prominent feature of agglomerating coal, an empirical relationship between swelling and porosity may exist without necessarily implying that swelling is a consequence of porosity. In fact, swelling and porosity may be consequences of a third factor, such as cross-linking density.

2.3.3. Resolidification

Resolidification is usually attributed to a series of cracking reactions followed by condensation and polymerization. A large number of free radicals and small molecules are generated by cracking. This is consistent with the observation that the original solvating agent, the bitumen, decomposes at ca. 480 °C, before resolidification of the coal to form a semicoke [31]. Because of the loss of hydrogen-donating and solvating agents, which would otherwise stabilize the free radicals, the solid material polymerizes forming semi-coke. This viewpoint is supported by the fact that the semicoke is deficient in hydrogen compared to the precursor.

2.4. Coke Microstructure and Mesophase Formation

The properties of cokes are determined by their microstructural characteristics. The structure – property relationship is, however, difficult to establish for coke because of its extreme heterogeneity in chemical constitution

and physical structure. Nevertheless, considerable progress has been made since the 1920s, primarily with the aid of optical microscopy.

The most significant industrial use of coke is in the production of iron and steel. Only prime coking coal produces coke appropriate for blast furnaces, where reactivity and stability under thermal stress are required [39], [40]. These requirements are met by metallurgical coke.

In general, the principal feature of the coke microstructure is the anisotropy of the organic coke substance as observed by optical microscopy [41–45]. The critical role of an intermediate plastic phase (carbonaceous mesophase) in the development of the characteristic anisotropic structures was first recognized in 1965 [46], [47]. Subsequent research has been devoted to the significance of mesophase formation during the carbonization of coking coal [48], the effect of coal rank and chemical constitution on mesophase formation [49–53], the use of optical and scanning electron microscopy [54], and the chemistry of mesophase formation [55–59]. These investigations may help to improve coke manufacture by modifying the microstructure through the development of a carbonaceous mesophase.

2.4.1. Microscopic Characterization

Optical microscopy is the principal means of analyzing coke morphology and anisotropic structures [54], [57]. The resolution limit of the optical microscope is ca. 0.2 µm. Optical anisotropy is an expression of structural anisotropy on the same scale [60].

For microscopic examinations, polished coke sections are viewed in plane-polarized light [61]. The appearance of the polished surface is termed the optical texture. Isotropic and anisotropic structures can be distinguished on the basis of different behavior [62], [63]. A common technique employs *reflection interference colors* [63]. These are yellow, blue, and dark purple for anisotropic materials and light purple for isotropic materials. Thus, cokes can be characterized by color and the shape and size of the isochromatic areas [54].

Differences in optical activity between isotropic and anisotropic cokes are due to differences in the range of crystallographic order [55]. The crystallographic order of isotropic coke is considered to be only small in scale; i.e., the parallelism of associated constituent lamellar molecules extends over short distances (ca. 1 – 5 nm). Although the structure can be claimed to be anisotropic for 1 – 5 nm, it is essentially isotropic to the light beam because this range is far below the resolution of the optical microscope (ca. 200 nm). However, for anisotropic coke, the range of crystallographic order extends from 0.3 to ca. 200 µm; in the light beam, the material has bulk anisotropy [55].

An optical microscopic classification of the organic solid residues derived from the hydrogenation of bituminous coal can be applied to coke obtained by carbonization. Table 2 includes the type of macerals and the transient phases responsible for coke microstructures. The formation of the transient, fluid phases (vitroplast and mesophase) is indicative of fusion (or plasticity) during carbonization and is limited to certain bituminous coals.

The term *vitroplast* designates a plastic or formerly plastic carbonization product of vitrinite that, unlike the starting material, is optically isotropic (e.g., the particle marked VP in Fig. 7). In coke it is characterized by flow structures and spherical morphologies.

Figure 7. Optical micrograph of the surface of solids from the carbonization of a low-volatile bituminous coal in an entrained-flow reactor (temperature: 900 °C; residence time: 0.15 s; heating rate: 10^4 °C/s)
VP: Vitroplast; SC: Semicoke; FS: Fusinite

The semifusinite maceral can also make a small contribution to the formation of spherical vitroplast. Further alteration of vitrinite and the spherical vitroplast derived from it is seen in the development of *cenospheres.* This term was

Table 2. Optical microscopic classification of solid carbonization products [64]

∗ Abbreviation.

first used to designate structures formed by rapid heating of pulverized coal [65], [66]. A cenosphere is defined as a reticulated hollow sphere composed of ribs or frames and windows (e.g., the particle marked CS in Fig. 8). Cenospheres are formed by the gas liberated within vitroplast spheres during the plastic stage [64].

Figure 8. Optical micrograph of the surface of solids from the carbonization of a high-volatile bituminous coal in an entrained-flow reactor (temperature: 900 °C; residence time: 0.15 s; heating rate: 10^4 °C/s)
∗ CS: Cenosphere.

In contrast to vitroplasts, the *mesophase* is optically anisotropic (e.g., the particles marked SC in Figs. 7 and 9) and represents the main route for the formation of anisotropic structures in coke. It is considered to be a unique, ordered, fluid system consisting of high-molecular-mass, planar molecules. The solid product formed via a mesophase is called a semicoke, a term used in a more general sense for the solid products of low-temperature (500 – 600 °C) carbonization of coking coals or heavy hydrocarbon feedstocks, such as coal – tar and petroleum pitches.

Both vitroplasts and cenospheres may develop intrinsic anisotropic structures (depending on the conditions of carbonization) while retaining their characteristic morphology. Another type of anisotropy in coke is associated with the unreacted vitrinite fragments. The distinction among these anisotropic microconstituents has a significant bearing on coke properties [64].

Figure 9. Optical micrograph of the surface of solids from the carbonization of a low-volatile bituminous coal in a packed-bed reactor showing extensive mesophase development (temperature: 900 °C; residence time: 1 h; heating rate: 10 °C/min)
∗ SC: Semicoke.

Scanning electron microscopy (SEM) is also useful for examining the microstructural characteristics of solids [67]. Its high resolution (ca. 3 nm) and depth of focus permit characterization of surface topography at very low and high magnifications (up to ×200 000). Specimens are examined by sweeping a finely focused electron beam across the surface. The resulting signals include secondary electrons, backscattered electrons, and characteristic X-rays. In the examination of coke, the most useful signal is the variation in secondary electron emission with changing surface topography. Optical microscopy and SEM are complementary techniques for coke characterization, providing structural and topographical information, respectively [55].

2.4.2. Carbonaceous Mesophase

The important properties of cokes, including mechanical strength and reactivity, are governed by the arrangement of the constituent carbon atoms. The principal features of the atomic arrangement are the alignment and size of *carbon crystallites.* The highest degree of alignment is seen in natural graphite crystals, which consist of extended layers of fused hexagonal rings of carbon atoms. This structure, with an interlayer spacing of 0.3354 nm, is approached by certain carbons manufactured from coal – tar and petroleum pitches and by polynuclear aromatic hydrocarbons on heating at 2500 – 3000 °C. Depending on their behavior when heat-treated, carbonaceous solids can be classified as graphitizing or nongraphitizing, e.g., coke and char, respectively, in the case of coal-derived solids.

Although the crystallite alignment in carbonaceous solids is only observable after heating at 1000 °C, crystallite alignment starts during carbonization over a narrow temperature range near 450 °C [57]. This stage, coincident with plasticity development, is characterized by the formation of carbonaceous mesophase, which leads to the anisotropic structures found in cokes. The shape and size of these anisotropic structures usually determine the behavior of the coke [68]. Substances that form graphitizing coke via a mesophase include the vitrinites of medium-volatile coking coal, coal – tar and petroleum pitches, polymers such as poly(vinyl chloride), and polynuclear aromatic compounds such as anthracene.

Lignites, thermosetting resins, polymers such as poly(vinylidene chloride), and hydrocarbons such as biphenyl do not form mesophase; instead, they produce isotropic nongraphitizing coke commonly referred to as *char* [57].

An outstanding characteristic of carbonaceous mesophase is the prevailing *molecular order,* which represents an intermediate state between totally isotropic liquids and anisotropic solid crystals. A crystal is characterized by long-range order. Isotropic liquids, on the other hand, possess no long-range order [69]. In liquid crystals, some but not all of the long-range order is maintained. The state is neither crystalline nor strictly liquid, and in 1922 the term *mesophase* was proposed [70–72]. The plastic, anisotropic phase formed during carbonization is designated interchangeably as liquid crystal or (carbonaceous) mesophase.

Of the several types of *liquid crystals,* the nematic (threadlike) type is the most relevant to carbonaceous mesophase [73]. Nematic liquid crystals separate from the isotropic liquid as anisotropic spherical droplets that eventually coalesce to give nematic domains. The molecular arrangement is envisaged as rod-shaped, similarly sized molecules lying parallel to each other but with no stacking order.

The parallel alignment of the molecules in carbonaceous mesophase and the separation from the isotropic liquid in the form of spheres suggest the behavior of nematic liquid crystals. The molecular units of carbonaceous mesophase are, however, disk-shaped and widely varied in size [74]. Furthermore, the formation of carbonaceous mesophase usually involves irreversible chemical processes, in contrast to the physical and reversible formation of nematic liquid crystals. Carbonaceous mesophase consists essentially of large polynuclear aromatic hydrocarbons [75]. Mesophase spheres formed during the carbonization of pitch may contain smaller molecules incorporated in the matrix of planar condensed-ring compounds (see Fig. 10) [74]. This gives a molecular mass distribution in the range of 400 – 3000 or even more.

Figure 10. Nematic molecular order of carbonaceous mesophase comprised of methyl-substituted polynuclear aromatic compounds connected by methylene bridges and biaryl linkages [74], [76]

The most commonly observed arrangement of molecules in mesophase spheres is the *Brooks – Taylor configuration*, in which layers of planar molecules lie parallel to the equato-

Figure 11. Optical micrographs showing the stages of mesophase formation during the carbonization of a decant oil in closed-tubing reactors (temperature: 500 °C; reaction time: 15 min, 30 min, 1 h, and 2 h, respectively)
A) Nucleation. B) Growth. C) Coalescence. D) Semicoke (flow domains)

rial plane around the polar axis, but curve to reach the surface at an angle [57], [77]. Other configurations have been observed, especially in the presence of induced magnetic fields and solid particles, e.g., carbon black [78], [79]. These configurations apparently show no different properties.

The uninhibited *formation and development of mesophase* occurs in three sequential stages: nucleation, growth, and coalescence. This progression, although clearly seen with the optical microscope in pitch and aromatic hydrocarbons, is not always observed during coal carbonization because of the inhibition of growth and coalescence or the very rapid formation of the final texture of the semicoke.

Nucleation is observed as the separation of anisotropic spheres from the isotropic melt, when they become sufficiently large (ca. 0.3 µm in diameter) to be visible (Fig. 11 A). This is a homogeneous process that does not require a specific site. Under favorable conditions, the spheres can grow at the expense of the isotropic melt (Fig. 11 B) and coalesce (Fig. 11 C) to form large domains of ordered regions (Fig. 11 D), which eventually solidify to semicoke. This type of extensive mesophase development (flow domains) leads to highly graphitizable coke.

If growth and coalescence are inhibited, irregularly shaped anisotropic spheres of small-scale order (0.3 – 10 µm grain size) are formed (see Fig. 12). These structures, frequently encountered in coal carbonization, are termed *mosaics.* A widely used classification, based on the shape and size of the anisotropic structures found in coke, is as follows [51]:

Isotropic no optical activity, uniform, light purple color on the surface
Anisotropic
Via mesophase dark purple, yellow, and blue areas of varying shape and size

Fine-grained mosaics irregularly shaped, isochromatic areas (ISIA), 0.5 – 1.5 µm long
Medium-grained mosaics ISIA, 1.5 – 5.0 µm long
Coarse-grained mosaics ISIA, 5.0 – 10 µm long
Coarse flow rectangular, flow-type structures 30 – 60 µm long; > 10 µm wide
Flow domains flow-type structures > 60 µm long; > 10 µm wide
Domains isometric structures > 60 µm in diameter
Basic anisotropy flat, featureless anisotropy associated with the parent unreacted (or slightly altered) vitrains from high-rank coals

Figure 12. The fine mosaic texture of a semicoke from the carbonization of a petroleum distillation residue in a closed-tubing reactor (temperature: 500 °C; reaction time: 1 h)

The sequential formation of mesophase is apparently not the sole mechanism leading to anisotropic structures in coal-derived coke. *Vitrains* from high-rank coals behave somewhat differently from coking and caking coals [49]. The inherent (basic) anisotropy of vitrain, which is rather featureless, is unchanged or converted directly to flow-type anisotropy. In this respect, it does not follow the progressive development of flow-type anisotropy.

Mesophase formation results from extremely complex and interdependent *physical and chemical processes* occurring during carbonization. The first chemical process is the rupture of weak bonds, breaking down the molecular network and forming free radicals, followed by such reactions as cyclization, aromatization, and polymerization.

The *fluid carbonization medium* at this stage can be envisaged as a dynamic chemical system, with increasing molecular mass and size [55]. When the planar molecules reach a critical concentration and size, van der Waals forces become sufficiently strong to establish parallel orientation. The resultant anisotropic miscellae separate from the isotropic fluid phase in the form of spheres. If the molecules are not sufficiently planar, parallel stacking is sterically hindered. The spherical shape of the separated anisotropic miscella results from the usual requirement of minimum surface area and surface energy at the interface of a two-phase system [55].

Figure 13. Isotropic texture of a char from the carbonization of a lignite in a packed-bed reactor (temperature: 900 °C; residence time: 1 h; heating rate: 10 °C/min)

The principles governing mesophase formation can be summarized as follows:

1) Heteroatoms and alkyl groups inhibit mesophase formation by cross-linking reactions, which impair planarity.
2) Naphthenic hydrogen promotes mesophase formation via hydrogen-transfer reactions, which retard cross-linking and increase fluidity.
3) Aromatic systems promote mesophase formation by virtue of their planarity and low reactivity.

These findings are based on studies of model compounds thought to resemble the building blocks of bituminous coal and petroleum feedstocks [56], [59], [80], [81]. In addition, mesophase formation depends on carbonization conditions.

The carbonization of coal of different rank produces coke with corresponding optical prop-

erties [53]. Low-rank coals (lignite and subbituminous) do not soften during carbonization, thus producing isotropic chars (see Fig. 13) [54].

The size of the anisotropic structures in coke generally increases with increasing coal rank (see Fig. 14) [51]. Whole coal behaves like vitrain. Caking coal with high volatile content forms isotropic coke containing small amounts of finegrained mosaics. With increasing rank up to the prime coking coals, these anisotropic structures become larger (5 – 10 µm) and more numerous.

Figure 14. Variation of coke optical texture with volatile matter content of the parent vitrains [51]

In coke from prime coking coal, the optical texture (apart from inorganic and infusible organic petrographic components) is essentially and continuously anisotropic, with structures varying in size from fine-grained mosaics to coarse particles up to 20 µm. The anisotropic structures in coke from fusing coal (high-to-low-volatile-content bituminous) develop mostly via mesophase formation.

Semianthracites, anthracites, and some noncaking low-volatile bituminous coals have no fluid stage during carbonization. The large anisotropic structures found in these cokes originate from the inherent anisotropy of the parent coal [49].

The variations in the optical texture of coke from coals of different rank reflect the differences in mesophase formation. These differences can be explained in terms of the variations in chemical constitution.

Coals become more aromatic with increasing rank, which is also associated with decreasing oxygen content and increasing incorporation of oxygen into cyclic structures [82], [83], [84].

In low-rank coal, most oxygen is in the form of carboxyl (–COOH) and hydroxyl (–OH) groups; both are reactive cross-linking agents. Oxygen in cyclic structures does not participate in cross-linking. In light of the principles discussed in this section, increasing aromaticity and decreasing oxygen content can explain the improvement in mesophase formation with increasing coal rank.

Carbonization conditions also affect mesophase formation. These effects are due to changes in the rate of chemical and physical processes [85], [86].

2.4.3. Modification of Optical Texture and Properties

The most significant feature of the microstructure of metallurgical coke is the unique anisotropy that is associated with low porosity and takes the form of mosaics bridged by small flow-type structures in the pore wall [53]. Most macropores are hundreds of micrometers in size; the pore wall is of significant thickness [53]. The limited porosity provides a coke density suitable for blast furnace operations, whereas the bonding of the small growth units of the anisotropic structures strengthens the coke. In addition, the anisotropic and nonporous nature of the coke reduces reactivity toward carbon dioxide, as is desired in blast furnace operations.

Consequently, coke properties can be modified by altering the optical texture and morphology. This makes possible manufacture of metallurgical coke from the large reserves of noncoking coal of low rank.

Modification of mesophase formation has therefore, great value in improving coke. The cocarbonization of noncoking coal with coking coal or pitch is also useful [87], [88].

3. Yield and Distribution of Pyrolysis Products

3.1. Experimental Methods

The yield of pyrolysis products (gases, liquids, and solids) is determined by monitoring the loss of coal mass or the quantity of gas evolved. In the traditional determination of proximate volatile matter (e.g., ASTM or DIN), the yield is measured as the mass lost from a fixed bed at standard conditions. Deviations from these conditions can change mass losses significantly (see Fig. 15). Smaller samples in a standard crucible (shorter bed depths) and higher heating rates and temperatures increase volatile yield.

Figure 15. Effect of sample mass (bed depth), heating rate, and pyrolysis temperature on mass loss [89]

Symbol	Heating rate, °C/s	Temp., °C
△	6	750
○∗	14	950
□	22	1150
▲	0.5	750
●	0.5	950
■	0.5	1150

∗ Standard ASTM volatile matter test.

Yields are also increased by reducing gas pressure and particle size. Thus, the volatile-matter content is highly dependent on pyrolysis conditions and can exceed 150 % of the ASTM value (e.g., last line, Table 3). When volatile products are desired, increased yield is of great interest. Furthermore, factors that influence the product distribution are important because in many processes the liquids (not the gases) are of primary interest.

In contrast to coal gasification, for example, with its few and easily identified products, the prediction of yield and product distribution in coal pyrolysis is difficult. The extreme complexity of coal pyrolysis precludes accurate thermodynamic analysis. Moreover, the temperature and pressure are often ill-defined. In rapid pyrolysis, internal pressures as high as 100 MPa have been estimated [89]. The design of reactors and processes is usually based on experimental determination of the yield and product distribution as functions of temperature, heating rate, pressure, particle size, and coal rank [90].

problems. Particle temperature is usually estimated from measurements of gas temperature (by suction pyrometry) with the aid of a heat-transfer model. Particle residence time (≤ 1 s) is calculated from known or assumed trajectories by using an appropriate model for the fluid and solid dynamics. The total yield of volatile substances, when not obtained from material balances, is frequently determined from the mineral matter or ash in the coal or char. The distribution of volatile products is usually determined by gas chromatography or mass spectrometry.

The yield of volatile products in the pyrolysis of coals of different rank under different heating rates increases continuously with increasing temperature. This results from the existence of a hierarchy of bond energies in the structure of coals (see Fig. 1). In most cases, even at heating rates as high as 10 000 °C/s in entrained-flow reactors, pyrolysis is complete at ca. 1000 °C. For a longer residence time, a lower temperature is needed to achieve a particular yield, in accordance with Arrhenius-type behavior (see Chap. 4). In particular, the yield is a sensitive function of temperature for short residence times in entrained-flow reactors.

The effect of temperature, the most important influence on product distribution, is illustrated in Tables 4 and 5, and Figures 16 and 17. The influence of temperature on the distribution of volatiles obtained from rapid pyrolysis of a lignite (270 – 10 000 °C/s) is clearly seen in Figure 16. The yield of tars reaches a low maximum at relatively low temperature. The hydrocarbon gases consist mainly of methane, ethylene, and hydrogen. The oxygen-containing products, water, carbon dioxide, and carbon monoxide, dominate the gas composition. A result of this temperature dependence is that the pyrolysis products have a range of heating values. This is illustrated in Figure 18 for lignite and is typical of the problems associated with obtaining clean-burning fuel from low-rank coals.

of bituminous coal (Fig. 17). In both cases, as in all pyrolysis processes, the yield of char or coke is substantial, even at 1000 °C.

3.2.2. Heating Rate

The effect of heating rate on coal pyrolysis has often been misunderstood. If slow heating (e.g., 10 °C/min in fixed-bed reactors) is compared with rapid heating (e.g., 10 000 °C/s in entrained-flow reactors), the latter usually gives a better yield. In most such comparisons, however, the heating rate is not the only variable. A change from a fixed-bed reactor to an entrained-flow reactor involves a sharp decrease in the density of the pyrolyzing medium, with important implications for secondary char-forming reactions (see Section 3.3). However, when the only change is an increased heating rate (see Table 6 and Fig. 19), yield and product distribution are

Table 6. Effect of heating rate on product distribution from bituminous coals [90]

□ Total; ○ Char; ■ Gas; ● Tar [90]

3.2.3. Pressure

In the rapid pyrolysis of bituminous coal, yield usually decreases with increasing pressure (see Fig. 20). A drop in the yield of tar is not compensated by an increase in the yield of hydrocarbon gases, such as methane (see Fig. 21 and Table 7). Increased pressure evidently favors char-forming reactions, particularly cracking and polymerization.

Figure 19. Effect of time on pyrolysis mass loss from a lignite (pressure: 101.3 kPa of He; final temperature (if attained): 1000 °C; mean particle diameter: 70 µm)
● 10^4 °C/s; ◗ 3000 °C/s; ○ 650 °C/s; △ 180 °C/s [90]

3.2.4. Particle Size

As with heating rate, the effect of coal particle size has been difficult to determine. Changes in particle size are usually accompanied by changes in temperature and residence time. In entrained-flow systems, the calculated residence time is dependent on particle size. Obtaining identical temperature – time histories for a range of sizes is difficult; therefore, reports in the literature are conflicting.

As might be intuitively expected (see Section 3.3), larger particles give a lower yield of volatiles. Increase in char formation (due to

tar cracking or polymerization) is not compensated by increased yield of hydrocarbon gas (see Fig. 22 and Table 8).

3.2.5. Coal Rank

Coals over a wide range of rank can give yields of pyrolysis products that are higher than their standard content of volatile matter (as determined by ASTM proximate analysis) (see Figs. 16 and 17, Tables 4 and 9). The most important result is the high tar yield given by entrained-flow pyrolysis of bituminous coal.

3.3. Mechanism

The objective of most coal pyrolysis processes, whether fuels or chemicals are being produced, is to maximize the yield of gaseous and liquid products (coke production is a notable exception). This is achieved by reducing secondary char-forming reactions (cracking and polymerization) of high-molecular-mass products.

Figure 20. Effect of pressure on pyrolysis mass loss from a bituminous coal (final temperature: 1000 °C; mean particle diameter: 70 µm; residence time: 5 – 20 s). Nominal heating rate, ° C/s:
• 650 – 750; ◗ 3 000; ○ 10 000; - - - - - Proximate volatile matter (ASTM).

Cracking and polymerization can occur within and between the coal particles. These reactions are usually subject to surface catalytic effects and to the nature of the medium to which the primary products are exposed [91].

Volatile material can be driven from the interior of a coal particle by increasing the internal pressure or by reducing the external (ambient) pressure. High pressure gradients accelerate volatilization, thus reducing residence time within the particle, which decreases the probability of secondary reactions and char formation. This explains the effect of external pressure (shown in Fig. 20) and of high heating rates, which result in rapid heat transfer and a high rate of thermal decomposition. This higher rate of formation of volatiles increases the internal pressure and reduces char formation.

Figure 21. Effect of pressure on the yield and distribution of volatile products from a bituminous coal (final temperature: 1000 °C; mean particle diameter: 74 µm; heating rate: 1000 °C/s; residence time: 2 – 10 s) [90]

Minimizing interparticle secondary reactions also is important for a maximum yield of volatiles. This is achieved by minimizing particle loading. In entrained-flow reactors, particle loading is far lower than in fixed-bed reactors and the heating rate is far higher. Fluidized-bed reactors are intermediate between these two types.

When pyrolyzed, low-rank coal yields much less tar than bituminous coal (Section 3.2.5). In part this is due to the presence of high molecular mass aromatic units in high-rank coal, which

form liquid rather than gaseous products. Another factor is the presence of cations in low-rank coal. Acid washing removes these cations and substantially increases the yield of volatiles (see Fig. 23). This is attributed to a higher tar yield and the elimination of char-forming reactions catalyzed by the highly dispersed cations (principally Ca^{2+}).

Table 9. Effect of coal type on yields of gaseous pyrolysis products [90]

Figure 22. Effect of particle size on pyrolysis mass loss from a bituminous coal (pressure: 101.3 kPa of He; final temperature: 1000 °C; heating rate: 650 – 750 °C/s; residence time: 5 – 20 s) [90]

Various options are available when selecting the operating conditions of a pyrolysis reactor (see Chap. 6) [93]. Residence times of 0.1 s or less are attainable only in entrained-flow reactors; at the other extreme, residence times of 100 000 s or more are practical only in fixed-bed reactors. At low temperature (ca. 525 °C), the total yield of volatiles is low because thermal decomposition is incomplete. Entrained-flow conditions minimize secondary reactions and give the highest overall yield. Furthermore, high molecular mass products are stable at low temperature, and the product distribution favors liquids. At ca. 1000 °C, volatilization is complete, with a correspondingly high yield. Again, entrained-flow conditions reduce secondary reactions and increase overall yield. However, even under dilute conditions in entrained-flow reactors, high temperature causes substantial cracking and gives gas as the principal volatile product.

Figure 23. Effect of cations on pyrolysis mass loss from a lignite (pressure: 101.3 kPa of N_2; final temperature: 1173 K; mean particle diameter: 70 µm; heating rate: 10^4 °C/s)
□ Acid-washed; ◇ As received [92]

4. Kinetics

The practical importance of the kinetics of the processes described in Chapter 3 depends on the reactor type [90], [94], [95]. In *fixed-bed reactors*, such as coke ovens where the heating rate is ca. 100 °C/min or less, kinetics are not important. The time required for complete pyrolysis is much less than the time required for heating

to the final temperature, which determines yield and product distribution.

On the other hand, residence time at pyrolysis temperatures is important in *entrained-flow reactors,* such as pulverized-coal combustors and some modern pyrolysis reactors, which are increasingly important.

A simple kinetic treatment for determining the rate constants that define the size of a reactor or reaction zone is to assume first-order decomposition of the volatile matter in the coal:

$$\frac{\mathrm{d}V}{\mathrm{d}t} = k\left(V' - V\right) \tag{1}$$

where k = rate constant (s^{-1}), V = fraction of volatiles evolved at time t, and V' = total amount of volatiles in the coal.

Figure 24. Arrhenius diagram for first-order kinetics of coal pyrolysis [94]

The temperature dependency of the rate constant (Arrhenius diagram) is given in Figure 24 for a number of experimental studies using different coals and reaction conditions [94]. According to the Arrhenius expression $k = A\exp\left(-E/RT\right)$, where A is the preexponential or frequency factor, E the activation energy, R the ideal gas law constant, and T the temperature; the rate constant is only a function of T. The large discrepancies observed result mostly from differences in measured reaction conditions and variations in coal rank.

The magnitude of the effect of coal rank is debatable. In one report the kinetics of pyrolysis were found to be insensitive to changes in rank from lignite to bituminous coal [94]. A possible explanation for this observation is that rapid pyrolysis rates are not determined by the chemical process of bond rupture, but by the physical processes of heat or mass transfer.

The modeling of the complex pyrolysis process by a single first-order reaction is an oversimplification. Many alternative kinetic schemes, proposed to represent more closely the actual mechanism of coal pyrolysis, range from two independent parallel reactions corresponding to the postulated two components in coals [96], to 42 reactions of the postulated 14 different functional groups in coal [97].

A reasonable compromise, which incorporates process complexity and is a mathematically adequate yet physically reasonable kinetic model [98], is based on a hierarchy of bond energies in the coal structure (see Fig. 1). The pyrolysis is assumed to consist of a large number, i, of independent chemical reactions representing the rupture of various bonds within the coal structure:

$$\frac{\mathrm{d}V_i}{\mathrm{d}t} = k_i\left(V_i' - V_i\right) \tag{2}$$

where the symbols are analogous to those of Equation (1), with the subscript i denoting a particular reaction. The rate constants k_i are assumed to be of Arrhenius form and to differ only in the values of their activation energies. The number of reactions is assumed to be large enough to permit the activation energies E_i to be expressed as a continuous Gaussian distribution function

$$\mathrm{f}\left(E\right) = \frac{1}{\sigma\left(2\pi\right)^{1/2}}\exp\left[-\frac{\left(E - E_0\right)^2}{2\sigma^2}\right]$$

with

$$\int_0^\infty \mathrm{f}\left(E\right)\mathrm{d}E = 1$$

where E_0 = mean activation energy and σ = standard deviation.

The term $f(E)\,dE$ represents the fraction of potential volatiles that have an activation energy between E and $E + dE$,

$$\frac{dV'}{V'} = f(E)\,dE \tag{3}$$

The total amount of volatiles remaining in the coal is obtained by combining the contribution from each reaction, i.e., by integrating Equation (2) over all values of E by using Equation (3):

$$\frac{V'-V}{V'} = \int_0^\infty \left(\exp - \int_0^t k\,dt \right) f(E)\,dE \tag{4a}$$

or

$$\frac{V'-V}{V'} = \frac{1}{\sigma(2\pi)^{1/2}} \cdot \int_0^\infty \exp\left[-A \int_0^t \exp\left(-\frac{E}{RT}\right) dt - \frac{(E-E_0)^2}{2\sigma^2} \right] dE \tag{4b}$$

Equation (4) shows that in addition to the temperature – time history, four parameters are needed to correlate coal pyrolysis data. The total yield of volatiles, V', should be determined experimentally and is not necessarily equal to the ASTM volatile matter content.

This model represents a significant improvement over the single first-order reaction scheme. Curves drawn through the experimental points in Figures 16 and 17 were obtained by using this model.

If, for simplicity and convenience, the single first-order reaction model of coal pyrolysis is assumed, the treatment that in the past has been applied to complex continuous reaction mixtures [99] and more recently to model coal liquefaction [100] should be used. It results in a temporal distribution of activation energies rather than the spatial distribution just described. It considers coal to be composed of constituents C_i; pyrolysis results in products P_i,

$$\Sigma C_i \overset{[ar]}{\underset{i}{}}$$

where the pyrolysis of each constituent is a first-order reaction:

$$-\frac{dC_i}{dt} = k_i(T)\,f(C_i)$$

Because C_i and P_i are not identifiable chemical species, a grouping procedure is used:

$$\Sigma C_i = V$$

The first-order rate expression, analogous to Equation (1), becomes [101]

$$-\frac{dV}{dt} = k(T,V)\,f(V)$$

Thus, the first-order rate constant k is not only a function of temperature, but also of the concentration of the volatiles, i.e., of conversion or time of pyrolysis. Limited experimental evidence [102] suggests that k decreases with conversion because of an increase in the observed activation energy. This can be interpreted as the intuitively reasonable initial predominance of the rupture of relatively weak bonds in the coal structure.

The main conclusion from this brief analysis is that some of the variation in rate constants observed in Figure 24 can be attributed to the fact that the constants may not have been compared at the same level of conversion.

For optimization of product distribution, having rate parameters for the total yield of volatiles and for individual compounds is desirable. The principal issue is the number of reactions necessary to describe the pyrolysis. In particular, determination of tar evolution rates is difficult because the rates are dependent on the transport properties of the experimental system, as discussed in Chapter 3. In one report these rate constants seem to correlate equally well the pyrolysis of lignite, subbituminous coal, and bituminous coal [94]. This means that pyrolysis rates may be dependent only on the quantity of the various functional groups in the coal and not on its origin or type. This conclusion, if established as generally valid for chemically rather than physically controlled pyrolysis processes, would simplify the design of pyrolysis reactors.

5. Hydropyrolysis

Most coal conversion processes involve hydrogen transfer reactions; pyrolysis involves *hydrogen redistribution.* Free radicals formed by bond rupture usually capture hydrogen atoms

(see Fig. 2). Under entrained-flow pyrolysis conditions, the total yield of volatiles is typically 20 – 40 % higher than the ASTM volatile content of the coal, i.e., at least 30 – 40 wt % of the product is a solid. The available hydrogen is used primarily to stabilize gaseous radicals, such as methyl or ethyl, leaving the higher molecular mass radicals to polymerize and form char.

To reduce char formation and increase volatile yield, the coal is pyrolyzed in the presence of hydrogen (see Fig. 25) [103]. The effect is more pronounced at higher hydrogen pressure, but is not observed if pyrolysis in an inert atmosphere is followed by exposure to hydrogen. Coal can be converted completely to methane in a few seconds at 950 °C and 50 MPa of hydrogen [104]. These effects are not fully understood, but seem to resemble the effect of hydrogen in coal liquefaction, where external hydrogen stabilizes the free radicals formed by bond scission and inhibits char formation. Another possible role of hydrogen in hydropyrolysis is to attack the highly reactive, but transient nascent carbon sites. Aromatic carbon radicals are formed by cleavage of functional groups. Hydrogen reacts with these active sites eventually forming methane, and, thus, the overall yield of volatiles is increased.

Figure 25. Effect of hydrogen pressure during pyrolysis on the yield of volatiles from a bituminous coal
[a] Coal: 3.5 MPa of N_2. [b] Char: 3.5 MPa of H_2. [c] Coal: 3.5 MPa of H_2. [d] Coal: 6.9 MPa of H_2 [103]

The effects of hydrogen pressure on the yield and distribution of pyrolysis products is illustrated in Figures 26 and 27 (see also Table 10). As discussed previously (see Section 3.2.3), an increase in the pressure of an inert gas reduces the yield of volatiles. With hydrogen, however, the yield first drops (see Fig. 26), and then increases with an increase in pressure.

Figure 26. Effect of helium and hydrogen pressure on pyrolysis mass loss from a bituminous coal (final temperature: 1000 °C; mean particle diameter: 70 µm; residence time: 5 – 20 s)
○ He (10^4 °C/s); ◗ He (3000 °C/s); ● He (650 – 750 °C/s); △ H_2 (750 °C/s) [90]

Figure 27. Comparison of tar yields from pyrolysis and hydropyrolysis of a bituminous coal (mean particle diameter: 74 µm; heating rate: 1000 °C/s)
○ 0.1 MPa of He; ● 6.9 MPa of He; ▲ 6.9 MPa of H_2 [90]

Experimental evidence suggests that the principal effect of H_2 is not in preventing secondary char-forming reactions (see Fig. 27). The yield of tar under the experimental conditions employed decreased under high hydrogen pressure.

[e] Residence time: 3 – 10 s.
[f] HC = Hydrocarbon.

Table 11. Early pyrolysis processes [105]

Pyrolysis process	Final temp., °C	Products	Processes
Low temp.	500 – 700	more coke, high tar yield	Rexco (700 °C), cylindrical vertical retorts; coalite (650 °C), vertical tubes
Medium temp.	700 – 900	more coke, high gas yield, domestic briquettes	town gas (obsolete) and coke, phurnacite, using low-volatile steaming coal, pitch-bound briquettes carbonized at 800 °C
High temp.	900 – 1050	hard, unreactive coke for metallurgical use	foundry coke (900 °C); blast furnace coke (950 – 1050 °C)

In this instance, the detrimental effect of a high external pressure overcame the beneficial stabilizing effect of hydrogen. In the case of a bituminous coal and a lignite, the overall yield enhancement was due to an increase in methane production (see Table 10).

Pyrolysis and hydropyrolysis processes are depicted in Figure 28 from a kinetic viewpoint (see also Fig. 2). On thermal decomposition, the pores of coal particles are filled with reactive (e.g., radicals) and less reactive volatiles. The latter escape unchanged, whereas the former are either quenched and escape, are cracked, or polymerize. Active char (or coke) contains active sites that react with H_2 to give methane. The deactivated sites contribute little or nothing to the overall volatile yield. The corresponding kinetic expressions are given below [90]:

Pyrolysis:

$$V' = V''_{\mathrm{nr}} + V''_{\mathrm{r}} \frac{K_{\mathrm{c}}}{K_{\mathrm{c}} + k_1} = V''_{\mathrm{nr}} + V''_{\mathrm{r}} \frac{1}{1 + \frac{k_1 P}{k_{\mathrm{c}}}}$$

Hydropyrolysis:

$$V' = V''_{\mathrm{nr}} + V''_{\mathrm{r}} \frac{K_{\mathrm{c}} + k_2 P_{\mathrm{H_2}}}{K_{\mathrm{c}} + k_2 P_{\mathrm{H_2}} + k_1} + k_3 P_{\mathrm{H_2}}$$

The curves in Figure 26 were obtained by using these expressions.

6. Pyrolysis Processes

Pyrolysis and hydropyrolysis give gaseous, liquid, and solid products; a further hydrogenation step may be required. Fixed-bed processes (low heating rate) give the highest quality coke. They predominate commercially and

Figure 28. Kinetic model for coal pyrolysis and hydropyrolysis [90]
$* V_{nr} = V'_{nr}$. $** V'_r \leq V''_r$.

are often referred to as carbonization processes. Dilute-phase fluidized-bed and entrained-flow processes (high heating rate), suitable for high yield of gaseous and liquid products (see Chap. 3), are at various stages of precommercial development.

Pyrolysis processes can be classified as early (Table 11) [105] or contemporary (advanced). The *early processes* generally involved low-cost systems and were intended to produce solids (coke or char) rather than liquids.

Contemporary processes, on the other hand, have been designed to maximize production of liquid by using conditions (e.g., dilute phase, pressurized H_2, and rapid heating and quenching) that minimize secondary pyrolysis reactions. This requires more expensive equipment and severer operating conditions [93], [106].

6.1. Low-Temperature Pyrolysis Processes

6.1.1. Early Processes

Low-temperature pyrolysis (below 700 °C) was developed mainly to supply gas for public lighting and smokeless (devolatilized) solid fuel for home use. Byproduct tars were valuable as chemical feedstocks and could be converted to gasolines, heating oils, and lubricants. Commercial low-temperature coal pyrolysis was utilized extensively in Europe, but was almost abandoned after 1945 as oil and natural gas became widely available. Rising oil prices have reactivated interest in this process.

The many low-temperature processes developed in Europe can be classified as batch or continuous, vertical or horizontal, and directly or indirectly heated (see Tables 12 [107] and Table 13).

Retorts or byproduct coke ovens were employed. Horizontal retorts (D retorts), 2.5 – 6 m long, were usually grouped together to form a bank heated by flue gas, with manual loading and unloading. Vertical retorts, both batch and continuous, were preferred in the United States and Europe because they permit gravity loading and unloading [108].

Rates of heat-transfer and carbonization were increased by using steel refractories as materials of construction. Internal heating was sometimes necessary to accelerate heat transfer by circulating hot gas. Only noncaking or weakly caking coals were used in continuous vertical retorts because caking coal softens and flows, forming large masses of coke that stick to the retort walls.

Two noteworthy low-temperature pyrolysis processes are the Disco and Coalite processes. These were successful when most low-temperature processes failed [108], [109].

6.1.2. Contemporary Processes

Lurgi – Ruhrgas Process. The Lurgi–Ruhrgas process (see Fig. 29) for the low-temperature production of liquids from low-rank coals is in commercial use in Europe.

Crushed coal is rapidly heated in a mixer (f) to 450–600 °C by contact with recirculating char particles that have been heated by partial oxidation in an entrained-flow reactor. The gas from the mixer is freed of particulate matter in a cyclone (h) and is passed through a series of condensers (i) to collect the liquid products; the latter are hydrogenated to yield stable products.

The char constitutes ca. 50 % of the products, whereas liquid yield is ca. 18 %; the remaining 32 % is gas with a heating value of $(26-31)\times 10^6$ J/m^3.

Toscoal Process. The Toscoal process, an adaptation of the Toscoal II oil – shale retorting process, was developed at a pilot plant near Golden, Colorado, with a capacity of 22.5×10^3 kg/d.

Crushed dry coal is preheated in lift pipes with flue gas from a ball heater and is fed to a rotating pyrolysis drum containing hot ceramic balls. Pyrolysis at ca. 500 °C produces char and hydrocarbon vapors. The char is separated by a trommel screen and withdrawn. The balls are reheated and returned to the drum. Pyrolysis products are cooled and condensed to recover light gases and coal liquids.

6.2. High-Temperature Processes (Coke-Making)

6.2.1. Coke Ovens

High-temperature carbonization is employed primarily to produce blast-furnace and foundry cokes for use in iron and steel manufacture. The process is carried out in coke ovens at ca. 900 °C.

In the 16th century, coke was found to burn hotter and cleaner than coal [110]. The earliest type of coke oven, the so-called *beehive oven*,

was developed in the 1850s; its main characteristic is that the heat necessary for coking is produced by burning the volatile constituents within the oven [111], [112]. All the gaseous and liquid byproducts are lost, together with large amounts of heat.

Beehive ovens have persisted well into the 20th century with progressive improvements in design and operation, such as heat recovery systems and vertical flues to supply process heat to the coking chamber.

A parallel development during the 19th century led to *slot ovens.* At first, these were simple rectangular firebrick structures holding a layer of coal ca. 1 m deep; later they were equipped with external heating flues [87]. In a further development, volatile byproducts were collected and used as fuel.

By the 1940s, the basic design of *modern coke ovens* had been developed. The ovens were ca. 12 m long, 4 m high, and 0.5 m wide, equipped with doors on both sides. The air supply was preheated by the hot exit gas. The recovery of the waste heat created higher temperatures and increased coking rates [113]. Since the 1940s, the process has been mechanized and the construction materials have been improved without significant design modifications. Assemblies may contain up to 60 ovens as large as 14 m long and 6 m high. Because of heat transfer considerations, widths have remained 0.3 – 0.6 m. Each oven in the battery holds up to 30 t of coal and operates on a 15-h cycle [114].

The coking process illustrated in Figure 30. The coal is conveyed from storage bunkers (a) to blending (b) and crushing (c) units, and then to the coke oven bunker (d). The ovens are loaded from a mobile larry car (e) located on top of the battery. Coking takes place in completely sealed ovens (f). The byproduct vapors and gases are collected and sent to recovery and processing units.

After carbonization, the oven doors are opened and the ram (g) pushes the red-hot coke into a quenching car. The coke is transported to the quenching unit (h) and then dumped on a sloping wharf (i) for cooling and drying. The dry coke is transferred to the screening and loading unit (j).

6.2.2. Coke Properties

The properties of coke depend on the coal and the processing conditions employed. The particle size, mineral matter, and moisture content, which can be controlled, affect the bulk density of the coal. Rank and maceral composition determine the fluidity of the plastic phase formed at intermediate temperatures. Significant process conditions include the wall temperature, coking time, and oven width; the heating rate and final temperature also affect coke structure (see Section 2.4).

The coal is prepared for coking by washing, drying, sizing, preheating, briquetting, and blending, with or without addition of pitch or breeze (fine coke particles) [111]. Foreign matter is removed mechanically and particle size is adjusted. Preheating (up to ca. 600 °C) increases production by ca. 50 % and reduces coking time without loss of quality [111].

Briquetting, with or without binder, increases the strength of the coke produced and permits noncoking or poorly coking coals to be used to make metallurgical coke. Cold briquetting is performed below the softening point of the coal (ca. 400 °C) and hot briquetting above the softening point (450 – 520 °C) [113].

Coal blending improves coke properties and yield and permits the use of noncoking or weakly coking coals [115]. Blending may also prevent damage to ovens when high coking pressure develops.

6.2.3. Byproducts

Carbonization byproducts were important in the development of the organic chemicals industry, but their use has greatly diminished because of competition from petroleum-based products. The principal byproducts are tar and coke-oven gas. Gas produced in the early slot ovens was used for domestic heating. Coal tar can be processed by petroleum-refining techniques. High-temperature tar can be fractionally distilled; three oil cuts are taken and a solid residue remains [33], [116]:

1) *Light oil* ($bp < 200$ °C), composed primarily of benzene, toluene, xylenes, and styrene.

2) *Middle oil* (*bp* $< 370\,^{\circ}$C), containing tar acids (phenols), tar bases (e.g., pyridine, anilines, and quinolines), and neutral oils (naphthalene).
3) *Heavy oil* (*bp* $< 550\,^{\circ}$C), containing aromatic compounds, such as anthracene, phenanthrene, carbazole, and chrysene.
4) *Coal tar pitch* (solid residue), consisting of a wide range of polycondensed aromatic compounds; it can be used as a binder for coal briquetting.

Byproducts that are obtained more cheaply from petroleum are no longer recovered exhaustively from coal tar.

6.2.4. Formed-Coke Processes

The preparation techniques and reactor configurations employed by some of the coking processes developed since the 1960s are different. Among these, the formed-coke processes have been the most successful (see Table 14). The term "formed coke" is used to describe cokes obtained by the carbonization of briquettes of weakly coking or noncoking coals. These processes provide the possibility of using weakly coking or noncoking coals, of controlling coke size to improve blast furnace operation, and of continuous operation in a contained system.

Blast furnace tests of these cokes have been successful. They are usually higher in moisture, volatile matter, sulfur, and reactivity to carbon dioxide, and lower in abrasion resistance than conventional metallurgical cokes [87].

6.2.5. Environmental Aspects

Coking plants create environmental problems like other large installations producing dusty materials and gaseous and liquid effluents [86]. Gas and volatile emissions may arise from leaks. Coal and coke particulates may be discharged during loading and unloading, and water used for quenching may be contaminated.

Particulate, volatile, and gas emissions can be reduced by using sheds or traveling hoods with dust and fume collectors [87]. Polluted water must be treated in wastewater plants. In some plants, dry quenching is used instead of water quenching, and the coke is cooled by gas or steam in a closed system. A further advantage of this process is that energy can be recovered via sensible heat and combustible gases.

In addition to air pollution, machinery and working conditions are hazardous. Plant location and accident prevention require serious consideration.

Table 14. Formed-coke processes [87], [113], [117]

Process (Country)	Raw Materials	Process steps
FMC (USA)	noncoking or coking coals and tar	1) oxidation and carbonization of coal in fluidized beds 2) cold briquetting of char with tar 3) preheating and carbonization of briquettes
DKS (Japan)	noncoking, coking coals and pitch	1) cold briquetting of coal with pitch 2) carbonization of briquettes
HPNC (France)	weakly coking, coking coals and pitch	1) cold briquetting of coal with pitch 2) carbonization of briquettes
BFL (FRG)	high-volatile noncoking coals and coking coals or pitch	1) carbonization of noncoking coal 2) hot briquetting of char with coking coal or pitch 3) carbonization of briquettes
ANCIT (FRG)	low-volatile noncoking coals and coking coals	1) flash heating of low-volatile noncoking coal 2) hot briquetting of char with coking coal 3) reheating of briquettes
Sapozhnikov (former states of the USSR)	high-volatile weakly coking coals and low-volatile weakly coking coals	1) flash heating of coal 2) hot briquetting 3) carbonization of briquettes
CCC-BNR (USA)	high-volatile noncoking coals and coking coals on pitch as binder	1) preheating of high-volatile coal 2) hot briquetting of char with binder 3) carbonization of briquettes

Table 15. Characteristics of selected pyrolysis processes [93]

Process	Reactors	Temperature, °C	Pressure, MPa	Yield, % (dry)			
				Coke	Tar and oil	Gas	H_2O
COED	fluidized-bed	290 – 565	0.12 – 0.19	62	21	14	3
Occidental	entrained-flow	610	0.3	56	35	7	2
Rockwell	entrained-flow	845	3.5	46	38	16	–

6.3. Contemporary Hydropyrolysis and Pyrolysis Processes

The three processes shown in Table 15 illustrate the principles described in Chapter 3. Their main objective is production of liquid hydrocarbons, for which entrained-flow conditions are the most favorable. However, char or coke is still the principal product in all three processes; its efficient use is one of the main issues in their economic analysis. The use of hydrogen in the Rockwell process reduces char production to some extent but as discussed in Chapter 5, this is achieved primarily by increasing the yield of gas, not liquids.

The *Coal Oil Energy Development (COED) process* (see Fig. 31), is a part of the COGAS process for complete conversion of coal to gases and liquids. The residual char from pyrolysis reacts with H_2O and O_2 in a fluidized-bed gasifier (g) to produce the hot synthesis gas, a mixture of CO and H_2. The synthesis gas serves as fluidizing and heat-transfer medium in the pyrolysis reactors (p_1–p_4).

The conditions in the gasifier do not permit complete conversion to gases. Part of the char that leaves is recycled to the pyrolysis section, where it provides additional heat for the endothermic devolatilization. The entrained fine particles and the remaining char are burned in a combustor (c). The hot flue gas is also recycled to the pyrolysis section to provide more heat.

This brief description illustrates the principal technical issues involved in the evaluation of pyrolysis processes: the type of contact between solids and fluids; the method of supplying heat; and the amount and fate of the residual char. In this context, several features of the

Figure 31. COED pyrolysis process [93]
$p_1 - p_4$) Pyrolysis reactors; g) Fluidized-bed gasifier; c) Combustor

COED process increase the production of liquids. The countercurrent flow of solids and gases (or vapors) and the increasing operating temperatures in the various pyrolysis stages help to reduce cracking by avoiding subsequent exposure to higher temperatures. The relatively dilute medium in the fluidized beds also helps to reduce the probability of secondary interparticle reactions.

Figure 32. Occidental pyrolysis process [118]
a) Char burner; b) Cyclone; c) Reactor; d) Cyclone; e) Oil collection system; f) Liquid upgrading; g) Char desulfurization plant

The low final temperature favors production of liquids. However, the heating rates are relatively low and intraparticle secondary reactions may still occur. The use of internally generated and recirculated hot gas and char to provide energy for devolatilization has the advantage of efficiency but it introduces a degree of complexity.

Figure 33. Effect of temperature on the distribution of products from a subbituminous coal in the Occidental process (pressure: 21 kPa of N_2; particle size: 80 % passing a 250 µm screen, 60 mesh; residence time: 1.5 s) [118]

The complete internal utilization of the coal is a virtue of the COED/COGAS process. The relatively low final pyrolysis temperature forms a

char that is highly reactive and, thus, suitable for gasification with steam. The resulting synthesis gas is a highly valuable and versatile product that can be converted, for example, to a natural gas substitute by methanation.

Figure 34. Effect of residence time on tar yield in the Occidental process (pressure: 21 kPa of N_2; particle size: 80 % passing a 250 µm screen, 60 mesh)
□ Subbituminous coal (649 °C); △ Bituminous coal (607 °C); ○ Bituminous coal (660 °C) [118]

Entrained-flow reactors are favored by a new generation of coal-conversion processes for several reasons. Both fixed-bed and fluidized-bed reactors need auxiliary equipment to avoid difficulties in processing of agglomerating bituminous coal. The fusion of coal particles during pyrolysis can block these reactors. In the COED process (Fig. 31), for example, where bituminous coal is the preferred feedstock because of its potentially high liquid yield, one of the stages (p_2) introduces oxygen cross-links into the coal structure and subsequently reduces or eliminates thermoplasticity (see Chap. 2), thus preventing agglomeration.

High throughputs are possible in entrained-flow reactors. The very dilute medium reduces the probability of particle agglomeration. Furthermore, rapid heating and a short residence time sharply reduce the importance of the plastic phase of pyrolysis of bituminous coals.

Finally, as discussed in Chapter 3, these conditions maximize the yield of volatiles and favor production of chars that may be sufficiently reactive to give valuable products, as in the COGAS process. Less reactive chars serve as fuel.

In the *Occidental process* (see Fig. 32) [118], the reactor operates at ca. 625 °C, thus maximizing production of liquids. Heat is supplied by mixing the coal with recirculated char that is made incandescent by partial combustion. The conditions for entrained flow require particles smaller than 200 µm (typically 80 % passing through a 60 mesh screen) and, thus, pulverization is necessary in contrast to fixed-bed

Figure 35. Rockwell hydropyrolysis process [119]

and fluidized-bed processes. The residual char is usually desulfurized for sale as "smokeless" fuel.

The effect of temperature and residence time on product distribution is shown in Figures 33 and 34.

The *Rockwell hydropyrolysis process* (see Fig. 35) incorporates the entrained-flow reactor as a minor component; other operations are similar to those encountered in petroleum refining. The hydrogen feed is preheated by partial combustion. After hydropyrolysis lasting 0.02 – 0.2 s, the products are rapidly quenched to prevent secondary char formation. A maximum liquid yield is obtained at an intermediate reactor temperature [119]. Changing hydrogen pressure affects product distribution, but not the yield of liquids; very high pressure is apparently needed to stabilize the reactive fragments in the absence of a solvent [119].

1. Introduction [1 – 4]

Cobalt, Co [*7440-48-4*], is a metallic element. Along with iron and nickel, it is one of the first-row transition-metal members of group VIII of the periodic table (old IUPAC recommendation; according to the new IUPAC recommendation, cobalt belongs to group 9). Its electronic configuration is [Ar] 3 d^7 4 s^2, giving it an atomic number of 27. The relative atomic mass of cobalt is 58.9332. Only one of its isotopes, ^{59}Co, is stable and occurs naturally; the other 12 known isotopes are radioactive and have the following mass numbers (half-lifes in parentheses): 54 (0.2 s), 55 (18.2 h), 56 (80 d), 57 (270 d), 58 (9 h), 58 (72 d), 60 (10.1 months), 60 (5.3 years), 61 (99 months), 62 (1.6 months), 62 (13.9 months), and 64 ($<$ 28 s).

The γ-rays emitted in the decay of ^{60}Co have energies of 1.17 and 1.33 MeV, and these taken with the 5.3-year half-life of the isotope provide a widely used source of radioactivity for use in food sterilization, radiography, and radiotherapy as an external source. The isotope is also used in chemical and metallurgical analysis and in biological studies as a radioactive tracer. The ^{57}Co isotope decays by electron capture to give ^{57}Fe, the most widely used isotope in γ-resonance (Mössbauer) spectroscopy [5].

Pure metallic cobalt has few applications, but its use as an alloying element and as a source of chemicals makes it a strategically important metal. End uses of cobalt-containing alloys include superalloys for aircraft engines, magnetic alloys for powerful permanent magnets, hard metal alloys for cutting-tool mate-

rials, cemented carbides, wear-resistant alloys, corrosion-resistant alloys, and electrodeposited alloys to provide wear and corrosion-resistant metal coatings. Cobalt chemicals, among their many applications, are used as pigments in the glass, ceramics, and paint industries; as catalysts in the petroleum industry; as paint driers; and as trace metal additives for agricultural and medical use. About 36 % of the worldwide annual production of cobalt is converted to chemicals, whereas high-temperature and magnetic alloys account for 41 % and 14 % of the consumption, respectively. Detail on all aspects of the science and technology of cobalt in general reviews [1 – 4] can be supplemented by reference to published abstracts [6, 7].

History. Although very little cobalt metal was used until the 20th century, its ores have been used for thousands of years as blue coloring agents for glass and pottery. Blue glazed pottery found in Egyptian tombs and dated at ca. 2600 B.C. has been found to contain cobalt, as have Persian glass beads dating from 2250 B.C. The Portland vase in the British Museum provides evidence that cobalt pigments were used by Greek glassworkers around the beginning of the Christian era. Cobalt-containing materials were also used to impart blue coloration to Chinese pottery during the Tang (600 – 900 A.D.) and Ming (1350 – 1650 A.D.) dynasties and to Venetian glass produced in the first part of the 15th century. The brilliant blue pigment used for these purposes can be produced by fusing an ore containing cobalt oxide with potash and silica to produce a vitreous material called smalt, which is powdered to produce the pigment. The secret of making the pigment was apparently lost during the Middle Ages and rediscovered during the 15th century. LEONARDO DA VINCI was one of the first artists to use the rediscovered blue pigment when painting "The Madonna of the Rocks." In the 16th century, P. WEIDENHAMMER produced a blue pigment, which he called zaffre, from the silver – cobalt – bismuth – nickel – arsenate ores found in Saxony. The next development in the use of cobalt-containing materials was the discovery, early in the 18th century, that solutions containing bismuth and cobalt could be used as sympathetic inks. The invisible writing obtained by using the inks became green when heated, with the color change apparently due to the presence of cobalt. It was not until 1735 that G. BRANDT, a Swedish scientist, first isolated cobalt metal as an impure sample by reducing an ore; in 1780 T. O. BERGMAN showed that the metal was in fact an element. The use of cobalt as a metal dates from 1907, when E. HAYNES patented a series of cobalt – chromium alloys named Stellites that were the forerunners of modern superalloys. In 1930 it was shown that addition of cobalt to certain alloys of iron, nickel, and aluminum enhanced their properties as permanent magnets.

From the 16th to the 19th century, the world's supply of cobalt — mainly as smalt and zaffre — was produced in Norway, Sweden, Hungary, and Saxony. Outside of Europe cobalt-containing ores were worked in Burma from 1651 and in New Caledonia from 1864. Major developments in cobalt recovery in the 20th century have stemmed from the discovery of new ore bodies and improvements in the methods of winning the metal from ores. Cobalt-containing copper ores were discovered in Zaire in 1914, and extraction of cobalt from the ores began in 1924, whereas recovery of cobalt from pyrite roasting residues was started in Germany in 1926. Mining of cobalt – nickel – gold – silver ores began in Morocco in 1932, and production of cobalt from copper – cobalt ores began in Zambia in 1933. The Outokumpu copper – cobalt – zinc deposit was discovered in 1913 and has been exploited on a large scale since 1928. In 1940 the International Nickel Co. (INCO) introduced a method of recovering cobalt from nickel ores, and from 1952 to 1955 the production of cobalt by the Canadian companies, Falconbridge Nickel Mines and the Sherritt Gordon Mining Co., began. Developments include the commissioning in 1975 of a cobalt refining plant based on a combination of pressure leaching, solvent extraction, and electrowinning by the Sumitomo Metal Mining Co. in Japan, and centering of interest on Laterite ores, particularly in Australia.

Worldwide production of cobalt in 1997 was just over 28 000 t, but this is expected to increase to 34 000 t/a.

The production of cobalt is usually subsidiary to that of other metals, such as copper and nickel, and its output cannot be significantly increased without a corresponding increase in the markets of the primary metals. Another important factor in the economics of the supply of cobalt is the

fact that a large proportion of the world's ore comes from one country, Zaire, and is therefore dependent on the political stability of that country. Cobalt is regarded as a strategic metal and is stockpiled in some countries.

The name cobalt is derived from the Greek word κόβαλος or the German word kobold for goblin or evil spirit. The term kobold was applied by miners in the Harz mountains of Germany to an ore that gave no metal when smelted and that also produced highly toxic fumes of arsenic oxide.

2. Physical Properties [1 – 4]

The physical and mechanical properties of cobalt metal are susceptible to variations because of variations in the structures of metal samples arising from a slow cubic to hexagonal phase transformation. The data quoted in this section are for the highest purity metal available; details of the effects of impurities on the properties of cobalt are to be found in a review by W. Betteridge [8].

Cobalt exists in two allotropic modifications, a close-packed hexagonal ϵ-form stable below ca. 400 °C and a face-centered cubic α-form stable at high temperature.

The transformation temperature is 421.5 °C. The free energy change associated with the transformation is low, being ca. 500 J/mol for the $\epsilon \rightarrow \alpha$ change and ca. 360 J/mol for the $\alpha \rightarrow \epsilon$ change; this accounts for the slowness of the transformation. The mechanism of the phase change is martensitic and involves dislocation movements on the octahedral planes of the cubic lattice. Grain size affects the stability of the two allotropes, with finer grain size favoring the cubic high-temperature form. For this reason the fine grain sizes found in cobalt powders, sponge, thin films, and fibers are responsible for the retention of essentially cubic structures down to ambient temperature. The cubic form is also favored by the presence of a few percent of iron in the lattice. Table 1 shows the cell parameters and other properties of the allotropes. The density of the metal decreases with increasing temperature and shows an anomalous fall of ca. 0.15 % at the transformation temperature. The liquid density just above the melting point is 7.73 g/cm^3, and at 2000 °C it is 7.26 g/cm^3.

Table 1. Properties of the allotropic forms of cobalt

Hexagonal ϵ-form	
Cell dimensions	
(ambient temperature)	a = 0.250 71 nm
	c/a = 1.6233
(417 °C)	a = 0.2541 nm
	c/a = 1.631
Density (20 °C)	8.832 g/cm^3

Stacking fault energy	
(20 °C)	31×10^{-7} J/cm^2
(370 °C)	20.5×10^{-7} J/cm^2
Cubic α-form	
Cell dimension	
(ambient temperature)	a = 0.35441 nm
(520 °C)	a = 0.35688 nm
(1398 °C)	a = 0.36214 nm
Density	
(ambient temperature)	8.80 g/cm^3
(1495 °C)	8.18 g/cm^3
Co – Co interatomic distance	0.251 nm
Stacking fault energy	
(500 °C)	13.5×10^{-7} J/cm^2
(710 °C)	18.5×10^{-7} J/cm^2

Thermal Properties. The *melting point* of cobalt is 1495 ± 2 °C, and its boiling point at normal pressure is 2800 ± 50 °C. The *vapor pressure* of cobalt varies from less than 10^{-5} Pa (at 1250 °C) to greater than 10^5 Pa (at 3200 °C). The *heats of fusion and vaporization* of cobalt are 17.2 and 425 kJ/mol, respectively. The *thermal conductivity* (λ) of the metal falls steadily with increasing temperature; there is no marked change in conductivity at the transformation temperature, but the data show a minimum in the region of the Curie temperature at 1121 °C. The values of λ at 0, 100, and 800 °C are 102, 85, and 50 W m^{-1}, respectively. The *heat capacity* of cobalt rises steadily with increasing temperature. There is only a slight inflection in the c_p vs. T curve at the transformation temperature, but a large change does occur at the magnetic transformation (see page 4). The *thermal expansion coefficient* of hexagonal cobalt depends on the orientation of the crystals and, for example, is 14.62×10^{-6} K^{-1} along the $\langle 0001 \rangle$ and 10.96×10^{-6} K^{-1} along the $\langle 1120 \rangle$ direction (at 20 °C). The average value for polycrystalline cobalt is 12.14×10^{-6} K^{-1}. The curve of the coefficient versus temperature shows a sharp change at the transformation temperature because of the

volume expansion of ca. 0.36 % associated with the phase change from hexagonal to cubic crystals. Cubic cobalt has a higher mean thermal expansion coefficient with values of (14.2, 15.7, 16.0, and 16.8) $\times 10^{-6}$ K^{-1} at 200, 400, 600, and 750 °C, respectively.

Mechanical Properties. The mechanical properties of cobalt are critically dependent on the purity of the metal and its thermal history. For well-annealed samples of high-purity cobalt, the *Vickers hardness* at normal temperature has values between 140 and 160 N/mm^2. The Vickers hardness of annealed cobalt decreases with increasing temperature to values of under 50 N/mm^2 at 750 °C with no marked change at the phase transformation. Microhardness studies on zone-refined single crystals of the metal show variations with crystal orientation and give values between 81 and 250 N/mm^2. Electrodeposited cobalt has high hardness (270 – 310 N/mm^2), presumably because of its fine grain size.

Measurements of elastic properties on polycrystalline bars of high-purity sintered metal annealed at 1000 °C give a *Young's modulus* of 211×10^3 MN/m and a *shear modulus* of 82 $\times 10^3$ MN/m at room temperature. The moduli decrease with increasing temperature, with the shear modulus showing an inflection and the Young's modulus a hysteresis at the phase change. For single crystals the moduli do vary with crystal direction, as shown in Table 2. Values of *Poisson's ratio* for cobalt are found to be in the range of 0.29 – 0.32.

Table 2. Elastic moduli at 20°C for cobalt along different crystal directions

Crystal direction	Young's modulus, 10^3 MN/m^2	Sheer modulus, 10^3 MN/m^2
1120	174	62.2
1010	175	62.2
1012	169	74.1
0001	213	62.4

Vacuum-melted, hot-worked cobalt annealed at 800 – 1000 °C has *tensile strengths* of 800 – 875 MN/m^2 and an elongation of 15 – 30 %. Air-melted samples are much less ductile. Cobalt has a maximum *ductility* at 500 °C, and this is the best working temperature for the metal, although the vacuum-degassed metal free from lead, sulfur, and zinc, can be hot-rolled in the temperature range of 600 – 1000 °C. Both elongation and tensile strength values show changes at the phase transformation.

The activation energy for *creep* is higher for hexagonal cobalt than for the cubic form; the values near the phase change temperature are 540 and 190 kJ/mol, respectively. The hexagonal crystals have lower values of friction and wear than the cubic crystals. The *friction coefficient* of cobalt rises steeply at temperatures above 300 °C to values of ca. 1.6 at 400 °C. The low coefficient associated with the hexagonal form is due to easy slip on the basal plane accompanied by the formation of a surface layer with the basal planes oriented parallel to the surface. In actual applications, however, the frictional and wear behavior of the metal will be determined by surface oxide films.

Magnetic Properties. Pure cobalt has the highest known Curie temperature. Hexagonal cobalt is ferromagnetic at all temperatures, but the cubic form becomes paramagnetic at 1121 $\pm$ 3 °C. The magnetic properties of single crystals show marked anisotropy. For hexagonal crystals at ambient temperature, the *c*-axis is the direction of easiest magnetization, but with increasing temperature magnetization becomes easier in a direction perpendicular to the *c*-axis; however, at ca. 250 °C the metal is magnetically isotropic. At even higher temperature, the *c*-axis becomes the most difficult to magnetize. Near the phase change temperature, the direction of easiest magnetization of the cubic form is along the $\langle 111 \rangle$ cube diagonal. Differences between this and other directions diminish with increasing temperatures until, at 1000 °C, the cubic form is magnetically isotropic.

The magnetic properties of polycrystalline samples of cobalt depend on the purity of the metal and its thermal history; this applies particularly to the development of preferred orientation. Magnetic anisotropy can, for example, be developed by slowly cooling the metal over the phase transformation temperature range in a strong magnetic field. Typical values for magnetic property parameters are listed in Table 3. The magnetorestrictive behavior of cobalt is also strongly anisotropic and reaches a maximum value for hexagonal crystals of $\Delta l/l = -27 \times 10^{-6}$ in a magnetic field of 560 kA/m along

the ⟨1120⟩ direction. The volume magnetorestriction shows a maximum contraction of 10^{-6} in a field of 480 kA/m and a magnetorestrictive expansion when the fields are above 760 kA/m.

Table 3. Magnetic properties of cobalt

Curie temperature	1121 °C
Maximum permeability	3.1×10^{-4} H/m
Coercive force	707 A/m
Remanence	0.49 T
Saturation magnetization	1.79 T

Electrical Properties. The electrical resistivity and the temperature coefficient of the resistivity of high-purity (99.999 %) polycrystalline cobalt are given in Table 4. The cubic form has a lower resistivity than the hexagonal modification whenever the forms coexist. The resistivity of single crystals of cobalt shows a marked dependence on orientation.

Table 4. Electrical resistivity and temperature coefficient of resistivity for cobalt

Temperature, °C	Resistivity, 10^{-8} Ω m	Temperature coefficient, 10^{-11} Ω m/K
− 100	2.65	–
− 50	3.84	–
0	5.25	30
50	6.81	34
100	8.52	39
200	12.80	50
300	18.38	60
400	24.72	71
500	30.65	75
600	39.1	87
800	57.9	105
1000	78.5	100
1200	92.7	41
1400	100.0	34

Other Properties. The self-diffusion of cobalt in the temperature range between 1057 and 1306 °C follows an Arrhenius-type law, the *diffusion coefficient* being given by the formula 2.2 (exp − 295/*RT*). The rate of diffusion is very dependent on grain size, being about 10 times faster for powder-metal samples than for bulk samples prepared by melting.

The *optical reflectance* of polished cobalt at ambient temperature and near normal incidence increases with wavelength from 60 % (at 1 µm) to 97 % (at 12 µm). The reflectance is much less at high angles of incidence. The optical emission spectrum of cobalt is complex and has over 330 lines in the range of 974 – 201 nm. The most important lines for analytical purposes are listed in Table 5. The characteristic K α_1, K α_2, and K β_1 X-radiation from a cobalt target occur at 0.1789, 0.1793, and 0.1621 nm, respectively; the K absorption edge is at 0.1608 nm.

Table 5. Optical emission lines of cobalt used in atomic emission analysis

Wavelength, nm	Relative intensity	
	Arc source	Spark source
352.9813	1000	30
346.5800	2000	25
345.3505	3000	200
340.5120	2000	150

237.8622	25	50
236.3787	25	50
230.7857	25	50
228.6156	40	300

3. Occurrence [1, 2, 4, 9]

Cobalt occurs in nature in a widespread but dispersed form in trace quantities in many rocks, soils, and plants. It is also found in sea water and in manganese-rich marine nodules. The cobalt content of the earth's crust is about 20 mg/kg, whereas its concentration in sea water has been reported as being 0.1 – 1 parts in 10^9. The concentration of the element in marine nodules is usually 0.1 – 1 %. The largest concentrations of cobalt are found in mafic and ultramafic igneous rocks; the concentration of the element and the nickel – cobalt ratio decreases from ultramafic to acidic rocks, as shown in Table 6. The nickel – cobalt ratio changes because cobalt enters the lattice of early crystallizing magnesium silicates less readily than nickel. Sedimentary rocks contain varying amounts of cobalt, with average values of 4, 6, and 40 mg/kg being reported for sandstone, carbonate rocks, and clays or shales, respectively. During the formation of metamorphic rocks, very little movement or concentration of cobalt took place; hence, the levels of cobalt found in metamorphic rocks depend essentially on the amount of the element in the

original igneous or sedimentary source. Those formed from ultramafic or mafic sources contain an average cobalt content of ca. 100 mg/kg, whereas gneissic granites and metasedimentary rocks contain an average of 16 and 8 mg/kg, respectively.

Table 6. Average cobalt content of igneous rocks

Rock type	Cobalt content, mg/kg	Ni – Co ratio
Ultramafic	270	7
Gabbro	51	2.6
Basalt	41	2.5
Diabase	31	2.3
Intermediate igneous	14	1.9
Felsic	5	1.1

Under oxidizing conditions, cobalt shows a strong tendency to concentrate with manganese oxides. In the weathering process of mafic and ultramafic rocks to form laterites, nickel tended to be leached downward with magnesia and silica, whereas cobalt with manganese oxides was residually enriched near the surface of the deposit. The concentration of cobalt and other metals in marine nodules has been attributed to the strong ion-exchange properties of the submicroscopic particles of colloidal manganese dioxide from which the nodules were formed.

Cobalt is a major constituent of about 70 minerals [10] and is a minor or trace constituent of several hundred more, particularly those containing nickel, iron, and manganese. The minerals that have been mined or concentrated for their cobalt content and those that are relatively high in cobalt are listed in Table 7. The sulfide minerals include the copper-containing carrollite, which is one of the main sources of cobalt in Zaire, linnaeite found in Zaire, Zambia, and the United States, and cattierite, which is also present in ores from Zaire. The arsenide ores include smaltite, which is found in the silver – copper ores from Cobalt, Ontario and in Morocco, and skutterudite, the main cobalt mineral in Canadian and Moroccan deposits. The sulfoarsenide, cobaltite, is found in ore bodies in Zaire, Canada, and the United States. The oxide mineral heterogenite is a hydrated metal oxide containing varying amounts of cobalt and copper and is one of the main cobalt-bearing components of the Zaire deposits. The hydrated manganese – cobalt mineral, asbolite, is the source of most of the cobalt in ores from New Caledonia.

Table 7. Cobalt minerals

Mineral	CAS reg. no.	Cobalt content, %
Cattierite, CoS_2 (pure)	[*12017-06-0*]	47.8
Linnaeite, Co_3S_4 (pure)	[*1308-08-3*]	58.0
Siegenite, $(Co,Ni)_3S_4$	[*12174-56-0*]	20.4 – 26.0
Carrollite, $(Co_2Cu)S_4$	[*12285-42-6*]	35.2 – 36.0
Cobaltite, (Co,Fe)AsS	[*1303-15-7*]	26.0 – 32.4
Safflorite, $(Co,Fe)As_2$	[*12044-43-8*]	13.0 – 18.6
Smaltite, $(Ca, Ni)As_2$	[*12006-41-6*]	ca. 21
Glaucodot, (Co,Fe)AsS	[*12198-14-0*]	12.0 – 31.6
Skutterudite, $(Co,Fe)As_3$	[*12196-91-7*]	10.9 – 20.9
Heterogenite, CoO(OH) (pure)	[*12323-83-0*]	64.1
Asbolite	[*12413-71-7*]	0.5 – 5.0
Erythrite $(CoNi)_3(AsO_4)_2 \cdot 8 H_2O$	[*149-32-6*]	18.7 – 26.3
Gersdorffite, (Ni,Co)AsS	[*12255-11-7*]	(low)
Pyrrhotite, $(Fe,Ni,Co)_{x-1}S_x$	[*1310-50-5*]	up to 1.00
Pentlandite, $(Fe,Ni,Co)_9S_8$	[*53809-86-2*]	up to 1.50
Pyrite, $(Fe,Ni,Co)S_2$	[*1309-36-0*]	up to 13.00
Sphalerite, Zn(Co)S	[*12169-28-7*]	up to 0.30
Arsenopyrite, Fe(Co)AsS	[*1303-18-0*]	up to 0.38
Manganese oxide minerals		0.10 – 1.0

Ore Deposits. Cobalt is produced mainly as a byproduct of the mining and processing of the ores of other metals, particularly those of copper, nickel, and silver, but also those of gold, lead, and zinc.

The deposits of cobalt can be classified under the following headings:

1) *Hypogene deposits* associated with mafic intrusive igneous rocks. The massive and disseminated iron – nickel – copper sulfides containing cobalt are important examples of this type of deposit. They include the ore from the Sudbury district of Ontario, which has an average cobalt content of 0.07 %. The suite of ore minerals consists of pyrrhotite, pentlandite, pyrite, marcasite, cobaltite, and gersdorffite in veins stringers and disseminated grains within an igneous host rock of Precambrian age.
2) *Contact metamorphic deposits* associated with mafic rocks. Deposits of magnetite, chalcopyrite, and cobalt-containing pyrite, formed by contact metamorphism of carbonate rock by sills and dikes of diabase, gave the ore deposits at Cornwall and Morgantown in the United States.

3) *Lateritic Deposits.* The weathering of peridotite and serpentine generally gives laterite that is rich in iron, nickel, cobalt, and chromium. Commercially valuable deposits contain 40 –50 % iron, 1 – 2 % nickel, and 0.01 – 0.1 % cobalt. Major lateritic deposits occur in Cuba, New Caledonia, Australia, the United States, and Russia.
4) *Massive sulfide deposits* in metamorphic rocks, largely of volcanic sedimentary origin. These deposits consist mainly of pyrite and pyrrhotite and are mined in the United States.
5) *Hydrothermal deposits* are subdivided into two classes: vein deposits and replacement deposits. Some of these deposits are the only ones that have been mined specifically as sources of cobalt. In Canada, veins that contain as much as 10 % cobalt occur in the Cobalt-Gowganda region of Ontario, whereas veins in the Bou-Azzer area of Morocco contain an average of 1.2 % cobalt. Hydrothermal replacement deposits containing 0.5 % cobalt as gersdorffite are found in Burma and at Outokumpu in Finland; a copper-rich sulfide deposit contains 0.2 % cobalt mainly in linnaeite.
6) *Strata-bound deposits:* the copper – cobalt deposits of Zaire and Zambia are of this type. They occur in folded shale and dolomite and contain a number of minerals, including chalcopyrite, bornite, chalcosite, linnaeite, and carroleite. The ore bed is 6 – 24 m thick and currently provides the world's major source of cobalt.
7) *Deposits formed as chemical precipitates* usually contain chemically precipitated cobalt in associated marine manganese nodules.

Reserves. As generally accepted, there are $(3 – 5) \times 10^6$ t of minable cobalt reserves and a further $(4 – 5) \times 10^6$ t of potential reserves. Table 8 lists the reported reserves in a number of countries. However, the minable reserves do not have the same degree of profitability. Cuba has minable resources of cobalt, but provides only 5 % of the world production because its ore bodies are laterites with only small quantities of nickel and cobalt that are costly to refine. Zaire produces more than half of the world's cobalt because its ores can be treated more profitably.

In addition to the land-based reserves listed in Table 8, almost 6×10^9 t of copper is available in marine nodules if it can be recovered and worked economically.

4. Production

4.1. Concentration of the Ores [1, 2, 9]

The first stages of the production of cobalt from its ores involve the separation of cobalt-bearing minerals from the gangue and from minerals containing other desirable metals but not cobalt. The concentrates obtained by applying physical separation methods such as gravity separation or froth flotation to ores can increase the cobalt content to 10 – 15 % from cobalt-rich ores. However, in general, these processes only increase the level of cobalt from 0.1 – 0.6 % in ores to a few percent. The concentration procedures for the main types of ores are described in this section.

Arsenide Ores. Cobalt arsenide minerals have specific gravities of 6.5 – 7.2 g/cm^3 and can be separated at relatively large grain size by gravity methods. Concentrates containing 13 – 14 % cobalt have been produced by these methods from Moroccan ores at Bou-Azzer containing 2 % cobalt.

Sulfoarsenide Ores. The main mineral in this type of ore, cobaltite, can be effectively separated by froth flotation with xanthate at pH 4 – 5, although iron sulfide minerals are also floated under similar conditions and must be separated from the cobalt concentrate.

Sulfide Ores. The chalococite and carrollite fractions of the ores of the Shaba province in Zaire are floated together at pH 9.2 by using lime, xanthates as collectors, and triethoxybutane as the frothing agent to give a concentrate containing 43 – 53 % copper and 0.5 – 3 % cobalt. The copper – cobalt sulfide ores of Zambia are first treated to float the copper minerals selectively at pH 10.5 – 11; at this stage the presence of sodium cyanide depresses the cobalt minerals. These are subsequently activated by sulfuric acid and floated at pH 8.5 – 9 with sodium isopropyl xanthate; the concentrates contain up to 3.5 % cobalt. The flotation

Table 8. Cobalt reserves

Country	Reserves, t	Country	Reserves, t
Australia	295 000	New Caledonia	385 000
Brazil	>9 000	New Guinea	18 000
Burma	16 000	Philippines	159 000
Canada	250 000	Puerto Rico	68 000
Columbia	22 500	Solomon Islands	22 500
Cuba	1 048 500	former Soviet Union	181 500
Dominican Republic	89 000	Uganda	8 000
Finland	22 500	United States	>764 000
Guatemala	45 500	Venezuela	60 000
Japan	2 500	Zaire	1 920 000
		Zambia	370 000

process at the Outokumpu Keretti Mill first separates the copper minerals with xanthates at pH 11 – 11.5 in the presence of lime and sodium cyanide. The cobalt minerals are then floated at pH 9 to recover 65 – 75 % of the cobalt from an ore containing 0.23 – 0.31 % cobalt; the concentrate contains 0.7 – 0.82 % cobalt. The nickel – copper – cobalt sulfide ores of Ontario are first treated to separate the sulfide minerals from gangue, and the cobalt minerals are then contained in the nickel sulfide concentrate.

Oxide Ores. Two methods have been used on a commercial scale to float oxide ores. The *palm oil process* collects the concentrate in a 3 : 1 mixture of hydrolyzed palm oil and gas oil emulsified in carbonated hot water; this process can give concentrates containing 23 – 25 % copper and 2 – 3 % cobalt, representing a cobalt recovery of 50 – 70 % from the ore. The *sulfidization process* is used for mixed oxide – sulfide ores to float sulfide ores first and to concentrate oxide minerals subsequently in a xanthate flotation.

4.2. Extraction [1, 2, 9]

Cobalt can be extracted from concentrates and occasionally directly from the ore itself by hydrometallurgical, pyrometallurgical, and electrometallurgical processes. Although most methods of extraction are based on hydrometallurgy, cobalt concentrates, mattes, and alloys have been reduced to metal by pyrometallurgical methods. Most arsenic-free cobalt concentrates can, for example, be mixed with lime and coal and melted in a reducing atmosphere to give cobalt – copper – iron alloys. Two types of alloys are obtained, a *white alloy* containing ca. 40 % cobalt that is processed for cobalt and a *red alloy* containing ca. 4 % cobalt that is processed for copper. Recovery of copper from the red alloy produces a cobalt-rich slag that can be recycled with the ores. The hydrometallurgical processes involve (1) leaching of concentrates to give a cobalt-containing solution, (2) separation of cobalt from the other metal ions in solution, and (3) reduction of cobalt ions to metal. Electrometallurgical processes are used in the electrowinning of the metal from leach solutions and in refining the cobalt that has been extracted by hydrometallurgical or pyrometallurgical methods.

4.2.1. Leaching of Cobalt Ores and Concentrates

Cobalt can be leached from its ores and concentrates in both acidic and alkaline media. Processes involving acid-sulfate leaching include (1) treatment of oxide ore concentrates with sulfuric acid containing a reducing agent, (2) extraction of cobalt sulfate from sulfide ores following an oxidizing roast, (3) extraction following a sulfatizing roast, and (4) extraction by pressure leaching with sulfuric acid, often in the presence of oxygen; the *Chemico process* for the treatment of arsenic-containing ores is, for example, based on an acid pressure leach. Acid leaching processes based on hydrochloric acid extraction and chloridation roasting have also been used.

Figure 1. Flow diagram of the Gécamines process

Processes that involve the extraction of cobalt into alkaline solutions depend on the formation of the hexamminocobalt(II) species $[Co(NH_3)_6]^{2+}$, which remains in solution for long periods because of its kinetic stability, even though it has low thermodynamic stability. Ammoniacal leaching has been successfully applied to ores after a reducing roast, and the Sherritt Gordon process depends on ammonia solution pressure leaching.

Cobalt from Copper – Cobalt Concentrates. The copper – cobalt ores of Zaire and Zambia are treated by a sulfatizing roast in a fluidized-bed furnace to convert copper and cobalt sulfides into soluble oxides and iron into insoluble hematite. The calcine is subsequently leached with sulfuric acid from the spent copper recovery electrolyte. Oxide concentrates are introduced at this leaching step to maintain the acid balance in the circuit. Iron and aluminum are removed from the leach solution, and copper is electrowon on copper cathodes. A part of the spent electrolyte enters the cobalt recovery circuit and is purified by removal of iron, copper, nickel, and zinc prior to precipitation of cobalt as its hydroxide. In the final stages, this cobalt hydroxide is redissolved and the metal is refined by electrolysis and by degassing to remove any traces of hydrogen. Figure 1 shows the flow diagram of the process used at the Générale des Carrières et des Mines (Gécamines) plant in Luilu.

Cobalt from Nickel Sulfide Concentrates. Nickel sulfide concentrates can be treated by either roasting or flash smelting to give a matte from which nickel and cobalt can be recovered hydrometallurgically, or they may be treated directly by an ammonia solution pressure leach. In the *Sherritt Gordon process* used at Fort Saskatchewan in Canada, which is illustrated as a flow diagram in Figure 2, a feed of matte and sulfide concentrate, containing about 10 % nickel, 2 % copper, 0.4 % cobalt, 33 % iron, and 30 % sulfur, is pressure leached in autoclaves at 83 °C and 0.7 MPa (7 bar) with an ammoniacal medium. This converts most of the sulfide via thiosulfate and polythionate to sulfate and solubilizes nickel, copper, and cobalt as ammine complexes. Most of the copper in the leach solution is precipitated as copper sulfides when the solution is distilled to recycle ammonia. The solution is treated with hydrogen sulfide to re-

move any residual copper, and any sulfide or sulfamate remaining at this stage is converted to sulfate by a pressure oxidation hydrolysis reaction at 6.5 MPa (65 bar). The solution then enters reduction autoclaves, where nickel powder is precipitated by reduction with hydrogen at 3.6 MPa (36 bar). The remaining solution, which contains 1 – 1.5 g/L of both cobalt and nickel, is treated in an autoclave with hydrogen sulfide to precipitate cobalt and nickel sulfides, which are subsequently leached with sulfuric acid at 140 °C and 6.4 MPa (64 bar). Iron is removed from this leach liquid at pH 2.5 – 3.0 by addition of ammonia solution. The cobalt(II) in solution is oxidized in air to give a very soluble cobalt(III) pentammine complex. Nickel is subsequently precipitated from the solution in two steps as a nickel ammonium sulfate. Cobalt powder is then added along with sulfuric acid to reduce the cobalt(III) pentammine complex to cobalt(II), which is finally reduced to cobalt powder by treatment with hydrogen at 120 °C and 4.6 MPa (46 bar).

Cobalt-containing mattes and mixed sulfide concentrates have also been treated by pressure leaching with sulfuric acid, for example, at Amax at Port Nickel in the United States, MRR in South Africa, Nippon Mining and Sumitomo Metals Mining Co. in Japan, and Outokumpu Oy in Finland. The flow diagram for the Outokumpu Kukkola plant (Fig. 3) is used to illustrate this type of cobalt recovery process. Two companies, Falconbridge in Canada and Norway and Société le Nickel in France, leach nickel mattes and sulfide concentrates in chloride media at ambient pressure. Falconbridge use a hydrochloric acid leach at 70 °C for about 15 % of their feed and a direct chlorine leach for the remainder. The leach medium used by Société le Nickel is chlorine in iron(III) chloride. At the INCO Copper Cliff plant nickel – copper mattes are cooled slowly and crushed prior to magnetic separation, which isolates a nickel – copper – cobalt alloy. The alloy is smelted in a top-blown rotary converter, desulfurized by oxygen lancing, and granulated. Nickel is volatilized from the granules as $[Ni(CO)_4]$ by the *INCO carbonyl process* to give a residue from which cobalt can be leached; the solution obtained allows cobalt to be electrowon after some purification steps.

Figure 2. Flow diagram of the Sherritt Gordon process

Cobalt from Laterite Ores. There has been an increasing interest in the recovery of cobalt from laterite ores. At least 150×10^6 t of laterite reserves containing up to 15 % of cobalt have been identified in Australia alone. It is predicted that this will lead to the production of about 10 000 t/a of cobalt in Australia and about 3000 t/a from both Papua New Guinea and New Caledonia.

Figure 3. Flow diagram of the Outokumpu process

The typical laterite ore process involves a pressure sulfuric acid leach of slurried ore at about 250 °C followed by neutralization and clarification of the leach solution to give a pregnant liquor containing dissolved cobalt and nickel at a pH of about 4.4. Extraction efficiencies for cobalt and nickel are claimed to be grater than 90 %. Cobalt is separated from the pregnant liquor by solvent extraction prior to precipitation as sulfide. The cobalt sulfide concentrate is then refined, redissolved, and the metal extracted by electrowinning.

Cobalt from Arsenide Ores. Arsenic-containing concentrates are roasted in a fluidized bed at 600 – 700 °C to remove 60 – 70 % of the arsenic present as arsenic(III) oxide. The roasted ores can be treated with hydrochloric acid and chlorine or with sulfuric acid to give a leach solution that can be purified by hydrometallurgical methods and from which cobalt can be recovered by electrolysis or by carbonate precipitation.

4.2.2. Separation of Cobalt from Other Metal Ions in Leach Solutions [9]

A major part of cobalt recovery from leach solutions is concerned with its separation from other elements. Because of the similarities in chemical behavior of cobalt and nickel, the separation of these two elements has been studied extensively and is well known. This section deals with chemical methods of separation of cobalt from nickel and with physicochemical methods of separation of cobalt from other elements.

Chemical Methods of Separation. The chemical methods of separating cobalt from other metals use the different solubilities and kinetic or thermodynamic stabilities of their compounds. The most important compounds that have been used in separation are hydroxides, carbonates, ammine complexes, double ammonium sulfates, sulfides, chlorides, and carbonyls; the cementation to metal is also utilized. For examples, see Section 4.2.1. The relative solubilities of cobalt(III) and nickel(II) hydroxides in the presence and absence of complexing agents and of cobalt(II) and nickel(II) carbonates in solutions containing NH_3 and CO_2 have also been used to separate these elements. Fractional crystallization of chloride-containing media can be used to concentrate cobalt in solution and nickel in solid nickel chloride dihydrate.

Physical Methods of Separation. Many physical methods have been used to separate cobalt from other elements, but the three most important are electrolysis (described in Section 4.2.3.), solvent extraction, and ion exchange.

In most solvent extraction processes, cobalt is extracted with a tertiary amine from chloride solutions, although cobalt and nickel can be separated from each other with phosphate or carboxylic acid reagents from ammoniacal sulfate

Figure 4. Flow diagram of the Sumitomo process

solutions. In the sulfuric acid leach process of Nippon Mining at Hitachi, solvent extraction is used to extract zinc from the leach solution with diethylhexyl phosphonic acid (DEHPA) at pH 2 – 3 prior to solvent extraction of cobalt with an alkylphosphonic acid. The Falconbridge and Société le Nickel processes both involve solvent extraction of cobalt from chloride solution with triisooctylamine (TIOA). The Sumitomo Metals Mining Co. uses a solvent extraction process to coextract cobalt and nickel with versatic acid. The extract is then stripped with hydrochloric acid, and cobalt is reextracted from the chloride solution with tri-*n*-octylamine (TNOA) to give an extract from which cobalt is stripped and electrowon. The flow diagram for this process is shown in Figure 4, and the solvent extraction process can be expressed in terms of the following chemical equations:

Extraction:

$$2\,\mathrm{RH\,(org)} + \mathrm{Ni\,(Co)\,SO_4\,(aq)} + 2\,\mathrm{NH_4OH} \rightarrow \mathrm{R_2Ni\,(Co)\,(org)} + (\mathrm{NH_4})_2\mathrm{SO_4\,(aq)} + \mathrm{H_2O}$$

Stripping:

$$\mathrm{R_2Ni\,(Co)\,(org)} + 2\,\mathrm{HCl} \rightarrow 2\,\mathrm{RH\,(org)} + \mathrm{Ni\,(Co)\,Cl_2\,(aq)}$$

Extraction:

$$\mathrm{Ni\,(Co)\,Cl_2\,(aq)} + 2\,\mathrm{R_3^1NHCl\,(org)} \rightarrow (\mathrm{R_3^1NH})_2\mathrm{CoCl_4\,(org)} + \mathrm{NiCl_2\,(aq)}$$

Stripping:

$$(R_3^1NH)_2CoCl_4(org) \xrightarrow{dil.\ HCl} 2\ R_3^1N \cdot HCl(aq) + CoCl_2(aq)$$

where RH is versatic acid in kerosene and $R_3{}^1N$ is tri-*n*-octylamine in xylene; (org) and (aq) are organic and aqueous phases, respectively.

4.2.3. Electrowinning [9]

Cobalt can be extracted and obtained as high-purity metal by electrolysis of sulfate or chloride solutions. Solutions of pH 1 – 4 are necessary for the electrowinning of cobalt, and the pH is often maintained by suspending cobalt hydroxide or cobalt carbonate in the electrolyte to consume the acid produced at the anode. Current densities of 5 A/dm^2 are used with current consumptions of ca. 6.5 kW h per kilogram of cobalt. Electrolytically refined cobalt is usually purer than 99.5 %.

5. Cobalt Powders [4, 11, 12]

5.1. Production

Cobalt powder can be produced by a number of methods, but those of industrial importance involve the reduction of oxides, the pyrolysis of carboxylates, and the reduction of cobalt ions in aqueous solution with hydrogen under pressure. Very pure cobalt powder is prepared by the decomposition of cobalt carbonyls.

Reduction of Oxides. Gray cobalt(II) oxide (CoO) or black cobalt(II)/cobalt(III) oxide (Co_3O_4) is reduced to metal powder with carbon monoxide or hydrogen. The reactions occur under conditions well below the melting point of the oxides or the metal. The purity of the powder obtained is 99.5 % with a particle size of ca. 4 µm, although the density and the particle size of the final product depend on the reduction conditions and on the particle size of the parent oxide. The finely powdered metal is stored at very low temperature.

Pyrolysis of Carboxylates. The thermal decomposition of such cobalt carboxylates as formate or oxalate in a controlled reducing or neutral atmosphere produces a high-purity (about 99.9 %), light, malleable cobalt powder with a particle size of ca. 1 µm that is particularly suitable for the manufacture of cemented carbides. The particle size, form, and porosity of the powder grains can be changed by altering the pyrolysis conditions.

Reduction of Cobalt Ions in Solution. Purified leach solutions containing cobalt pentammine complex ions can be treated in autoclaves with hydrogen under pressure and at high temperature to give an irregular chainlike form of the powder that is suitable for consolidation by direct strip rolling.

5.2. Uses

5.2.1. Cemented Carbides [4, 13]

One of the most important uses of metallic cobalt is as a bonding agent in cemented carbides that are used extensively as cutting tools for metals, rocks, and other high-strength materials (→ Hard Materials). No suitable substitute has been found for cobalt as a cementing agent for carbides. The important properties of cobalt for this use are (1) high melting point, (2) high-temperature strength, (3) the ability to form a liquid phase with WC at 1275 °C, (4) the ability to dissolve WC by the formation of an eutectic containing 10 % of WC at 1275 – 1350 °C, and (5) the ability to reprecipitate WC from solution as the mixture cools. The most commonly used cemented carbide, tungsten carbide containing 2 – 30 % cobalt, is manufactured as follows: pure cobalt powder is added to tungsten carbide (particle size ca. 1 µm), and the mixture is ball-milled for a long period by using hard metal balls. The mixed powders are then consolidated by cold pressing, by hot pressing at ca. 1300 – 1400 °C, by cold extension, or by slip casting to produce small artifacts, large artifacts, constant-section rods, and complex-shaped articles, respectively. The consolidated parts are sintered in a reducing atmosphere at 1300 – 1600 °C. The sintering process involves the formation of a liquid phase; the cobalt liquefies at ca. 1320 °C and dissolves tungsten and carbon from the carbide. When the mixture is cooled,

most of the tungsten and carbon reprecipitates, but the binder phase is much stronger than pure cobalt because enough tungsten and carbon are present to stabilize the metal in its cubic form. During the sintering process, the consolidated powders shrink by 20 %. The binding mechanism depends on (1) the liquid metal phase to wet the carbide particles so that surface tension forces help densify the sintered phases and (2) on the ability of the liquid to dissolve and retain traces of carbide impurities.

The properties of cemented carbides are controlled by the amount of cobalt present and the particle size of the carbide used. The hardness of the cemented carbides increases with decreasing particle size and with increasing cobalt content. The impact strength of cemented carbides is directly proportional to the cobalt content; it rises from less than 1 kg m for a sample with 6 % cobalt to ca. 2.5 kg m for a sample with 25 % cobalt in tungsten carbide with a particle size of 1.4 – 3.1 µm. The properties of cemented tungsten carbides can be improved by the addition of other carbides such as those of niobium, tantalum, or titanium.

Cobalt powders are also used as binders for the diamond tool industry [14].

5.2.2. Cobalt Powders in Powder Metallurgy and Cobalt-containing Metal [13]

Cobalt powders have been used in the formation of a number of alloy phases including maraging steel by hot extension of prealloyed powders, cobalt-based superalloys by consolidation of powders involving liquid phase sintering, fine-particle magnetic alloys, and bearing materials impregnated with low-friction substances such as graphite, lead, nylon, and molybdenum disulfide.

6. Cobalt Alloys [1 – 4, 9]

6.1. General

About 64 % of the cobalt is consumed in alloy compositions. The most important cobalt alloys are discussed in this article under the following headings:

- high-temperature alloys
- magnetic alloys
- hard metal alloys
- cobalt-containing high-strength steels
- electrodeposited alloys
- alloys with special properties

Solute metals in cobalt can be classified in terms of their effect on the phase transition (cubic to hexagonal) of the host metal. Those elements that raise the transition temperature are classified as *restricted-field components,* whereas those that lower the temperature are *enlarged-field components.* Some alloying elements must be classified as combined components because they both raise the $\epsilon \rightarrow \alpha$ transition temperature and lower the $\alpha \rightarrow \epsilon$ transition temperature. Table 9 lists some alloying elements according to their classification. The phase diagrams of a number of binary and ternary cobalt alloy systems have been reported [1, 3]. According to the phase diagrams, a number of binary alloys have stable hexagonal structures at high temperature and these may be of practical importance where the hexagonal structure is required, for example, to maintain low friction and wear characteristics. Alloys with high-temperature stable hexagonal lattices (temperature in parentheses) are cobalt – chromium, 90 : 10 (800 °C); cobalt – molybdenum, 90 : 10 (950 °C); cobalt – osmium, 60 : 40 (1250 °C); cobalt – platinum, 80 : 20 (650 °C); cobalt – rhenium, 80 : 20 (750 – 950 °C); cobalt –ruthenium, 70 : 30 (1100 – 1400 °C); cobalt – tungsten, 80 : 20 (950 °C).

Table 9. Classification of alloying elements in cobalt-rich binary alloys

Enlarged-field	Restricted-field	Combined
Al Nb	As Re	Au
B Ni	Cr Rh	Be
C Sn	Ge Ru	Ga
Cu Ti	Ir Sb	Pb
Fe Zr	Mo Si	Pd
Mn	Os Ta	V
	Pt W	

6.2. High Temperature Alloys (Superalloys) [13, 15]

Cobalt-based superalloys and cobalt-containing nickel superalloys are used in aircraft engines as turbine vanes and blades and in sheet form for exhaust case assemblies and burner liners. Cobalt-based superalloys are complex combinations of elements intended to accomplish one or more specific purposes. Normally the matrix is face-centered cubic. Commercial alloys are commonly hardened by carbide formation and by solid-solution strengthening. The properties responsible for the industrial importance of carbide-strengthened alloys are high creep strength at high temperature, high thermal fatigue resistance, good oxidation resistance, excellent hot corrosion resistance, an air melting capability, an air or argon remelting capability, good welding properties, and ease of casting. The effects of added elements on the properties of superalloys are listed in Table 10. A number of elements are detrimental to the alloy properties. Sulfur, for example, affects the ductility and must be kept at a concentration of less than 0.006 %. Other elements that have been reported to show deleterious effects are bismuth, lead, antimony, thallium, selenium, cadmium, mercury, tin, and silver. The cobalt-based alloys consist essentially of a cobalt – chromium matrix with ca. 20 % chromium, which provides major resistance to high-temperature corrosion. Up to 30 % of the cobalt can be replaced with nickel, and up to 15 % tungsten may be added as well as smaller levels of other beneficial metals. The carbon content lies in the range of 0.25 – 1 % for casting alloys and 0.05 – 0.4 % for hot worked alloys. Table 11 lists the compositions of several cobalt-based high-temperature alloys, indicating the alloys that are normally cast; Table 12 shows the stress rupture strengths for some cobalt-based superalloys.

The presence of carbides in the grain boundaries of superalloys is important in determining their mechanical properties. The grain boundaries are strengthened by carbides in one of two ways: (1) their precipitation as discrete particles in the grain boundaries hinders sliding by a pinning action and (2) the formation of a grain boundary skeletal network that can support load as well as hinder sliding. Both mechanisms also strengthen by limiting grain-boundary migration. Solid-solution strengthening is principally due to contents of chromium, tungsten, niobium, and tantalum, not to the precipitation of carbides. Table 13 lists the strengthening mechanisms in cobalt-based superalloys.

Table 10. Effects of several elements in cobalt superalloys

Element	Effect*
Chromium	improves oxidation and hot-corrosion resistance; produces strengthening by formation of M_7C_3 and $M_{23}C_6$ carbides
Molbydenum and Tungsten	solid-solution strengtheners; produce strengthening by formation of intermetallic compound Co_3M; formation of M_6C carbide
Tantalum and Niobium	solid-solution strengtheners; produce strengthening by formation of intermetallic compound Co_3M and MC carbide; formation of M_6C carbide
Aluminum	improves oxidation resistance; formation of intermetallic compound CoAl
Titanium	produces strengthening by formation of MC carbide and intermetallic compound Co_3Ti; with sufficient nickel produces strengthening by formation of intermetallic compound Ni_3Ti
Nickel	stabilizes the face-centered cubic form of matrix; produces strengthening by formation of intermetallic compound Ni_3Ti; improves forgeability
Boron and Zirconium	produce strengthening by effect on grain boundaries and by precipitate formation; zirconium produces strengthening by formation of MC carbide
Carbon	produces strengthening by formation of MC, M_7C_3, $M_{23}C_6$, and possibly M_6C carbides
Yttrium and Lanthanum	increase oxidation resistance

* M = metal.

The important properties of the alloys for high-temperature use are time-dependent creep, stress rupture, or fatigue strength at the operating temperature. Properties such as tensile strength, hardness, and modulus are not important for high-temperature operation, but do have an effect on manufacturing operations involved in the production of parts. The oxidation of uncoated cobalt-based superalloys can be quite severe, and protective coatings are required when the alloys are used in hot sections of turbines in jet engines.

Cobalt-containing Nickel-based Alloys. Most highly stressed components in high-temperature engineering use are nickel-based superalloys strengthened by the precipitation

of the intermetallic compound $Ni_3(TiAl)$. Addition of ca. 20 % cobalt improves the high-temperature properties of the nickel-based alloys. The influence of cobalt arises from several effects, namely:

1) Its relatively minor contribution to solid-solution hardening.
2) Its influence on the solubility of the matrix for titanium and aluminum. At temperatures below 1080 °C, the cobalt-containing alloys have a lower solubility for these metals than the cobalt-free alloys and, therefore, increase the amount of $Ni_3(TiAl)$ precipitated at a given level of alloying; this is a major factor in giving increased high-temperature strength.
3) Its effect on the formation of carbides in the grain boundary. The presence of cobalt increases the solubility of carbon in the matrix and modifies the carbides formed in the grain boundary.
4) It improves the hot workability.

The presence of cobalt in nickel-based alloys has a pronounced effect in decreasing the stacking fault energy, which results in a decrease in the creep rate of nickel or nickel – chromium phases.

6.3. Magnetic Alloys [1, 2, 4, 16, 17]

Cobalt is used in the manufacture of three main types of permanent magnet materials: quench-hardened carbon steels, nickel – iron – aluminum – cobalt (Alnico) [*12605-54-8*] alloys, and rare-earth cobalt alloys (→ Magnetic Materials).

Quench-hardened Carbon Steels. The addition of cobalt to quench-hardened steels increases the coercive force and the BH_{max}. The improved properties are mainly due to magnetorestrictive strain effects that increase the coercive force together with a small increase in saturation magnetization. Currently, magnet steels are used less, but they still have advantages in situations where the magnetic alloy must be machined and worked.

Table 12. Characteristic rupture strengths of selected cobalt- and nickel-based superalloys

C = cast alloy.

Nickel – Iron – Aluminum – Cobalt Alloys (Alnico Alloys). Nickel – iron – aluminum alloys (see also → Magnetic Materials) have a high coercive force, but are very brittle and must be cast into their final shape. Addition of cobalt to the alloys greatly improves their magnetic properties. The gains are progressive with increasing cobalt content up to 20 – 25 % cobalt. Typical compositions of cobalt-containing Alnico alloys are given in Table 14 along with their magnetic properties. The magnetic properties of these alloys, particularly remanence, can be improved by applying a strong external field to them as they cool from the solution treatment temperature. The resulting magnetic properties are anisotropic, being higher in the direction parallel to the field than perpendicular to it. The properties of anisotropic magnets can be further improved by careful control of thermal gradients during cooling, which results in the growth of columnar grains with the ⟨100⟩ crystal axes lying along the direction of growth. When these columnar alloys are subjected to a magnetic field during cooling, the magnetic properties are again markedly improved.

The permanent magnet properties of Alnico alloys depend on the separation of the original body-centered cubic lattice into two isomorphous phases: (1) a nickel – aluminum-rich nonmagnetic matrix and (2) magnetic iron – cobalt-rich precipitated particles that are epitaxially orientated in the matrix and elongated along one of the ⟨100⟩ directions.

The Alnico alloys can be prepared by casting in shell molds or by powder metallurgy. The use of powder metallurgy depends on a knowledge of the domain theory of ferromagnetism. In the process the particle sizes of the alloy powders used are reduced so that they approximate the size of single magnetic domains. The fine particles (0.02 – 0.05 µm) of the iron – cobalt alloys used can be prepared by thermal reduction of salts such as formates or oxalates or by controlled electrolysis of mixed iron – cobalt salt solutions.

Rare-Earth – Cobalt Alloys. The rare-earth – cobalt alloys often have the composition MCo_5, where M is a rare-earth metal, and contain 60 – 65 % cobalt (see also → Magnetic

Table 13. Strengthening mechanisms in cobalt-based superalloys

Mechanism	Comments
Carbide formation (MC, M_6C, $M_{23}C_6$, M_7C_3)	effective as strengthening agents but overaging a problem; optimum distribution not always achieved
Solid-solution hardening (Ta, W, Mo, Nb)	effective at temperatures above ca. 1095 °C, but not potent below this temperature
Intermetallics (Co_3W, Co_3Mo, Co_3Ti, Co_3Ta, σ-, μ-, or Laves phases)	overaging above ∼ 870 °C; possible deterioration of ductility and oxidation resistance due to σ, μ and Laves; appreciable hardening can be achieved below 815 °C
Grain structure (directional, single, fine)	directional solidification yields better thermal fatigue and ductility, but higher cost because of special processing; fine-grained more ductile, possible better fatigue but poorer creep
Dispersoids (ThO_2, other oxides, carbides)	expensive, technique very critical, no outstanding alloy yet developed
Minor elements (B, Zr)	fairly well explored, effective; excessive boron must be avoided due to low ductility and incipient melting
Eutectics (intermetallics)	requires further investigation, offers promise of high-temperature stability and good strength
Face-centered cubic to hexagonal close packing transformation and dislocation structure	field requires much more investigation before assessment can be made, question of stability
Fiber reinforcement	not enough information developed as yet
Combinations of the above	adds to expense so that properties developed must be improved enough for economic justification

Table 14. Composition and magnetic properties of Alnico alloys

Composition, %						Method of manufacture	Remanence, T	Coercive force, kA/m	BH_{max}, kJ/m^3
Co	Ni	Al	Cu	Ti	Nb				
3 – 5	21 – 28	11 – 13	2 – 4	0 – 1	–	Cast	0.55 – 0.75	36 – 56	11 – 12
12 – 14	16 – 20	9 – 11	3 – 6	0 – 1	–	Cast	0.65 – 0.80	40 – 50	13 – 14
17 – 20	18 – 21	8 – 10	2 – 4	4 – 8	–	Cast	0.6 – 0.7	60 – 72	14 – 16
23 – 25	12 – 15	7.8 – 8.5	2 – 4	0 – 0.5	–	field treated	1.2 – 1.3	46 – 52	40 – 44
32 – 36	14 – 16	7 – 8	4	4 – 6	–	field treated	0.0 – 0.9	110 – 140	40 – 45
24 – 25	13 – 15	7.8 – 8.5	2 – 4	–	0 – 1	columnar	1.3 – 1.4	56 – 62	56 – 64
32 – 36	14 – 16	7 – 8	4	4 – 6	0 – 1	columnar	1.0 – 1.3	110 – 140	60 – 74

Materials). The anisotropy that gives high coercivity in these alloys arises from a hexagonal lattice that has the direction of easy magnetization along the hexagonal axis. Single domain particles compacted in an external magnetic field retain the high coercivity of the individual particles. Exceptionally high values of coercive force have been obtained in these alloys — the values for alloys based on samarium or praseodymium are the highest and can be as high as 650 kA/m.

The rare-earth – cobalt magnets are normally manufactured by melting the components in a protective atmosphere. The cooled melt is then crushed and milled to a fine powder, again in a protective atmosphere, before it is compacted to shape in an applied field. Two dominant groups of rare-earth – cobalt magnets are in commercial production. One group is based on single-phase $SmCo_5$ [*12017-68-4*] and the other on precipitation-hardened alloys near the compo-

sition $Sm(Co, Cu, Fe)_{7.5}$. A large amount of the samarium in $SmCo_5$ can be substituted by neodymium, praseodymium, or the natural mixture of rare-earth metals (mischmetals); this either increases the saturation polarization or decreases the cost of the alloy components.

Cobalt is also the major component of zero magnetorestrictive amorphous alloys. These are metallic glasses with the lowest technically realized coercivities. They have no directionality in terms of their magnetic properties and are relatively hard and strong materials giving rise to low hysteresis eddy current losses. Their properties favor their use in applications such as magnetic shielding, magnetic heads, amplifiers, pulse transformers, and HV/HW transformers.

The uses of the magnets include focusing magnets in traveling wave tubes, magnetic bearings in ultrahigh-speed centrifugal separators and inertia wheels, and actuators, motors, and generators of various sizes from watches to 100-horsepower motors, including brushless motors. The magnetic properties of these alloys depend critically on their manufacturing history, but are characterized by an almost linear demagnetization curve between the remanence and coercive force. Typical magnetic properties of some of the MCo_5 magnets are listed in Table 15. The $Sm(Co, Cu, Fe)_x$ phase owes its coercive force to pinning of domain walls on coherent precipitates embedded inside the grains either of a M_2Co_{17} phase embedded in an MCo_5 matrix if $x < 7$ or discrete MCo_5 particles embedded in M_2Co_{17} for $x > 7.8$. The presence of copper is essential for this type of hardening, but it decreases the saturation polarization.

Table 15. Properties of MCo_5 magnets

Magnet	Remanence, T	Coercive force, kA/m	BH_{max}, kJ/m^3
$SmCo_5$	0.85	600	140
$Sm_{0.5}Pr_{0.5}Co_5$	0.95	600	176
(Mischmetal)Co_5	0.65	300	64
$PrCo_5$	0.94	660	150

6.4. Hard Metal Alloys [4]

Because of their inherent high strength, corrosion resistance, and ability to retain hardness at elevated temperature, cobalt-based alloys have been used extensively for over 50 years in wear-related engineering applications.

Cobalt – Chromium Alloys (Stellite Alloys). The Stellite alloys were developed around 1900 and over 20 compositions are now commercially available. They can be divided into two classes: (1) alloys of cobalt, chromium, tungsten, and carbon and (2) alloys of cobalt, chromium, tungsten, molybdenum, nickel, iron, and carbon. For special hard-facing applications, these alloys can also be modified by the addition of small percentages of silicon and boron.

The traditional *alloys of cobalt, chromium, tungsten, and carbon* contain ca. 30 % chromium with varying amounts of tungsten (4 – 17 %) and carbon (1 – 3.2 %). They are used primarily in lubricated or high-temperature wear applications. The composition of a typical tough-grade hard alloy is 30 % chromium, 4 % tungsten, and 1 % carbon, which has a Vickers hardness of 375 N/mm^2 at room temperature and of 100 N/mm^2 at 900 °C. A typical medium-grade hard alloy contains 30 % chromium, 9 % tungsten, and 1.5 % carbon and has hardness values of 470 N/mm^2 at room temperature and of 150 N/mm^2 at 900 °C. A typical hard-grade hard alloy contains 32 % chromium, 18 % tungsten, 2.5 % carbon and has hardness values of 600 N/mm^2 at room temperature and of 200 N/mm^2 at 900 °C.

The *Co – Cr – W – Mo – Ni – Fe – C alloys* contain 25 – 32 % chromium, 0 – 19 % tungsten, 3.22 % nickel, 3 – 10 % molybdenum, 5 – 20 % iron, and 0.1 – 2 % carbon in a cobalt base. The microstructure of the Stellite alloys consists of hard particles of Cr_7C_3 dispersed in a cobalt-rich solid-solution matrix. The adhesion and cavitation-erosion wear characteristics that have been attributed to the matrix alloy are influenced by a phase change from a strain-induced cubic form to a hexagonal form in the matrix alloy. The toughness and abrasion resistance of the alloys are, however, due mainly to the volume fraction of carbides and their morphology.

Cemented Carbides. The precipitation and applications of cemented carbides as hard alloys are discussed in Section 5.2.1.

6.5. Cobalt-containing High-Strength Steels [18]

Cobalt is not one of the elements commonly added to steels because its direct effects on the properties of steel are usually less than those achieved by other alloying elements. Cobalt is, however, an important component of steel when high strength is a requirement, and it is a unique alloying element in favoring the austenitic structure at the ferrite – austenite boundary and in raising the martensitic transformation temperature.

The addition of a few percent of cobalt to low-alloy steels that contain strong carbide-forming elements, such as molybdenum or tungsten, increases the tempering resistance of the steel. Solid-solution hardening of martensitic steels by the addition of cobalt is particularly noticeable in chromium stainless steels. High chromium ferritic and martensitic steels containing 6 – 7 % cobalt are used for high-temperature applications up to 550 °C. Cobalt is a particularly useful alloying element in controlled-transformation steels in which initial cooling of the steel gives austenite, which can be cold worked and subsequently transformed into martensite by tempering or refrigeration. A typical steel of this type contains 6 % cobalt.

Maraging steels are ultrahigh-strength alloys and contain cobalt, nickel, and molybdenum with 5 – 20 % cobalt. Cobalt plays an indirect role in the formation of intermetallic compounds containing minor alloy components such as titanium, which accelerates and enhances the hardening process. Cobalt also plays a prominent role in the short-range ordering of the solid solution that leads to additional hardening. The advantages of maraging steels are (1) good tensile strength and toughness that is maintained up to 350 °C and (2) their weldability either in the annealed or aged conditions without preheat or postheat stress-relieving treatments.

Cobalt (5 – 12 %) can be added to improve the hot hardness of high-speed tool steels.

6.6. Electrodeposited Alloys [9]

Protective coatings of electroplated nickel – cobalt alloys have been used since the mid-1930s. The 25 % cobalt alloy deposited from sulfate electrolytes is about three times harder than electroplated nickel and has about the same hardness as pure cobalt. The Vickers hardnesses of the electrodeposits vary with cobalt content, and for deposits from sulfamate – chloride solutions, they rise from ca. 200 N/mm^2 for nickel plate to ca. 540 N/mm^2 for a deposit containing 40 % of cobalt. The cobalt – nickel alloy deposits also have improved corrosion resistance in many environments and have been used in the production of mirrors, decorative coatings, and for electroforming. Electrodeposits of cobalt – tungsten alloys are of interest because of their hardness at high temperature. Hardness values in the range of 400 – 600 N/mm^2 are obtained for deposits with 30 % tungsten; this increases to 500 –700 N/mm^2 after heat treatment at 300 – 350 °C and remains as high as 650 N/mm^2 at 600 °C. These electrodeposited alloys have been used to improve the wear resistance of hot forging dies.

The magnetic properties of a number of electroplated alloys have attracted attention for use in recording systems and computer applications. The alloys with suitable magnetic properties include cobalt – iron, cobalt – nickel, cobalt – platinum, and cobalt – phosphorus.

6.7. Alloys with Special Properties

A number of cobalt-containing alloys have special applications; they are described in this section.

Dental Alloys. Cobalt – chromium alloys have been used in dentistry since the mid-1930s (→ Dental Materials). The most widely used alloy is Vitallium [*12629-02-6*], which is a cobalt-based alloy containing 30 % chromium, 5 % molybdenum, and 0.5 % each of carbon and silicon. The alloys are used for cast denture bases, complex partial dentures, and some types of bridgework. The properties of the alloys that make them suitable for dental applications are their good castability, resistance to tarnish, compatibility with mouth tissues, high strength and stiffness, and low density. A modified alloy is used for porcelain coatings for crown restorations; it enables the crown to be fused to metal bridges. Alloys containing 12 % chromium, 9 % nickel, 8 % titanium, and 1 % molybdenum

have expansion characteristics that match those of dental porcelain.

Surgical Implants. Cobalt – chromium alloys similar to Vitallium are used for surgical implants and for bone replacement and repair because they are very resistant to corrosion in body fluids. The best known prosthesis is hip joint replacement, but the alloys are also used for plates, screws, and nails for fracture fixations. Because the dynamic loadings on bone replacement implants amount to several million cycles artificial joints must also have high fatigue strength.

Low-Expansion Alloys. Cobalt is used as an alloying element in low-expansion iron – nickel alloys of the Invar type. The cobalt content can be up to 25 % and the alloys are used for sealing metals to borosilicate glasses. These alloys have a face-centered cubic solid solution structure that is ferromagnetic within the low-expansion temperature range. The low-expansion behavior is probably caused by a contraction that is due to magnetorestriction canceling out the normal thermal expansion of the alloy. Low-expansion behavior can also be found in the cobalt –chromium – iron alloy system and the composition with 54 % cobalt, 9 % chromium, and 37 % iron has an expansion coefficient close to zero over the temperature range from − 60 to + 60 °C.

Spring Alloys. The alloy Elgiloy is typical of the alloys used in springs. It contains 40 % cobalt, 20 % chromium, 15 % nickel, 7 % molybdenum, 2 % manganese, 0.15 % carbon, 0.04 % beryllium, and the balance being iron. After special treatment, this alloy has a Vickers hardness of 650 N/mm^2, an elastic limit of ca. 160 MN/m^2, and a tensile strength of 2300 MN/m^2.

Alloys with temperature-independent elastic moduli can be used as hair springs for watches and chronometers and for spring balances. Although many of the alloys used for this purpose are based on nickel, a series of cobalt-based alloys containing 50 – 60 % cobalt, 25 – 35 % iron, and 15 – 18 % chromium have suitable properties and have been used for this purpose.

Magnetic Recording Alloys. Much work has been carried out on the development of thin films of cobalt-containing alloys for use as magnetic recording materials [16]. The alloy films can be manufactured by vapor deposition, sputtering, ion-plating, and calendering. Several alloy compositions have been described for use in recording applications; they include cobalt – nickel, copper – nickel – zinc – phosphorus, cobalt – iron – magnesium – carbon, and cobalt – molybdenum – zirconium – niobium. Microcrystalline or amorphous films of the alloys are deposited on polymers and alloys such as Co – Ni (80 : 20), and Co – Mo – Zr – Nb (81 : 7 : 10 : 2) have been used. Video recording tapes with smooth surfaces have also been produced by depositing a ferromagnetic layer of γ-Fe_2O_3– Co powder. The magnetic properties of the films are important in recording applications. The films should have a nearly square *B/H* hysteresis loop and no magnetorestriction.

7. Cobalt Compounds [9, 20]

7.1. Chemical Properties of Cobalt

Cobalt is much less reactive than iron. It is stable to atmospheric oxygen unless heated. When heated, it is first oxidized to Co_3O_4 and then, above 900 °C, to CoO, which is also the product of the reaction between the red-hot metal and steam. The activation energy of the oxidation above 900 °C has been calculated as 155 – 160 kJ/mol. The metal does not combine directly with hydrogen or nitrogen, but it combines with carbon, phosphorus, and sulfur on heating. The reaction with sulfur is influenced by the formation of a low melting eutectic (877 °C) between the metal and the Co_4S_3 phase; the reaction between cobalt and sulfur is rapid above this temperature. Below 877 °C, a protective layer of sulfide scale is formed. In an atmosphere of hydrogen sulfide, cobalt also forms a scale of sulfide, but in air containing sulfur dioxide, a mixed oxide – sulfide scale is formed.

In bulk form, cobalt is resistant to many mild corrosive agents, but it is more readily attacked when it is finely divided. Table 16 gives the corrosion rates of cobalt in some aqueous media. Cobalt is strongly attacked by concentrated nitric acid at ambient temperature. The

metal dissolves slowly in dilute mineral acids, the Co^{2+}/Co potential being − 0.277 V.

Table 16. Corrosion of cobalt in aqueous media at 25 °C

Corrosive medium	Rate of cobalt corrosion, mg dm^{-2} d^{-1}
Distilled water	1.1
5 vol% Ammonia	5.3
10 vol% Sodium hydroxide	5.6
Conc. phosphoric acid	7.4
50 % Phosphoric acid (aqueous)	65.1
5 vol% Acetic acid	12.5
5 vol% Sulfuric acid	56.8
50 % Hydrofluoric acid (aqueous)	178.6

The solubility of oxygen in cobalt is 0.006, 0.013, 0.125, and 0.4 wt % (at 600, 1200, 1510, and 1700 °C, respectively). Nitrogen is only slightly soluble (40 mg/kg) in cobalt at its melting point; the solubility rises to 60 – 70 mg/kg at 1750 °C. The solubility of hydrogen in cobalt increases with temperature from 1 mg/kg at 700 °C to ca. 8 mg/kg at the melting point. The solubility of hydrogen in the liquid metal increases to ca. 20 mg/kg at 1500 °C and to ca. 27 mg/kg at 1750 °C.

The main oxidation states of cobalt are Co^{2+} [*22541-53-3*] and Co^{3+} [*22541-63-5*]. In acid solution and in the absence of complexing agents, Co^{2+} is the stable oxidation state, with oxidation to Co^{3+} being difficult.

$$\left[Co\,(H_2O)_6\right]^{3+} + e^- \rightarrow \left[Co(H_2O)_6\right]^{2+} \Delta E^\circ = 1.84V$$

The oxidation can be achieved by electrolysis or ozone, but the Co^{3+} ion is very unstable and is rapidly reduced to Co^{2+}, even at room temperature, with evolution of oxygen from the water. The solution chemistry of cobalt in acid solution in the absence of complexing agents is dominated by Co^{2+}. The most common species present is $[Co(H_2O)_6]^{2+}$, although the ions $[CoX_3]^-$, $[CoX_4]^{2-}$, and $[CoX_6]^{4-}$ (X = halide) are also found in solutions of hydrogen halides. Cobalt is often removed from solution as its sulfide, and it is interesting to note that although the precipitates of cobalt sulfide obtained by using H_2S are not readily soluble in dilute acids, those obtained by using Na_2S or $(NH_4)_2S$ are soluble. All sulfide precipitates become less soluble as they age in the atmosphere to form Co(OH)S. The cobalt dihalides (except fluoride) are also readily soluble in some organic solvents such as alcohol, acetone, and methyl acetate.

In alkali, Co^{2+} is more readily oxidized to Co^{3+}

$$CoO\,(OH)\,(s) + H_2O + e^- \rightarrow Co(OH)_2\ (s) + OH^- \qquad \Delta E^\circ = 0.17\ V$$

In the presence of complexing agents, oxidation is very easy in any solution because Co^{3+} has a particularly high affinity for complex formation. With N-donor ligands the redox reaction in the presence of ammonia is

$$\left[Co(NH_3)_6\right]^{3+} + e^- \rightarrow \left[Co(NH_3)_6\right]^{2+} \quad \Delta E^\circ = 0.1\ V$$

Oxidation of Co^{2+} solutions containing complexing agents can be achieved with air or hydrogen peroxide. Thus, the solution chemistry of cobalt in the presence of complexing agents is dominated by the complex chemistry of Co^{3+}. The sensitivity of the reduction potential of the Co^{3+}/Co^{2+} couple to different ligands whose presence renders Co^{2+} unstable to air oxidation is shown by the data in Table 17.

Table 17. ΔE° for some Co^{3+}/Co^{2+} couples in acid solution

Redox reaction	ΔE°
$[Co(C_2O_4)_3]^{3-} + e^- \rightleftharpoons [Co(C_2O_4)_3]^{4-}$	0.57
$[Co(EDTA)]^- + e^- \rightleftharpoons [Co(EDTA)]^{2-}$	0.37
$[Co(bipy)_3]^{3+} + e^- \rightleftharpoons [Co(bipy)_3]^{2+}$	0.31
$[Co(en)_3]^{3+} + e^- \rightleftharpoons [Co(en)_3]^{2+}$	0.18
$[Co(CN)_6]^{3-} + H_2O + e^- \rightleftharpoons [Co(CN)_5(H_2O)]^{3-} + CN^-$	− 0.8

EDTA = ethylenediaminetetraacetic acid; bipy = bipyridyl; en = ethylene diamine.

Cobalt(II) Compounds. Cobalt combines with oxygen to form cobalt(II) oxide [*1307-96-6*], CoO, which is stable above 900 °C. This oxide has the sodium chloride structure and is antiferromagnetic at ordinary temperature. When cobalt(II) oxide is heated at 400 – 500 °C in an atmosphere of oxygen, the cobalt(II,III) oxide, Co_2O_3 [*1308-06-1*], is formed. This mixed-valence oxide has the spinel structure

with cobalt(II) in tetrahedral sites and cobalt(III) in octahedral sites. Cobalt hydroxide [*1307-86-4*], $Co(OH)_2$, is a product of the hydrolysis of solutions containing Co^{2+} ions. The hydroxide is amphoteric, dissolving both in alkali, to give blue solutions containing the $[Co(OH)_4]^{2-}$ ion, and in acids. Cobalt(II) forms an extensive range of simple and hydrated salts with all of the common anions including acetate, bromide, carbonate, chloride, fluoride, nitrate, perchlorate, and sulfate. Many of the hydrated salts and their solutions contain the pink octahedral $[Co(H_2O)_6]^{2+}$ ion. Although complexes of cobalt(II) are generally unstable to oxidation, a number of octahedral species are formed, including (1) a series of $[Co(N-N)_3]^{2+}$ complexes with neutral bidentate donor ligands, such as ethylenediamine and bipyridyl, and (2) the acetylacetonates $[Co(acac)_2] \cdot 2\,H_2O$ and $[Co(acac)_2]$. Tetrahedral complexes $[CoX_4]^{2-}$ are usually formed with monodentate anionic ligands, such as chloride, bromide, iodide, thiocyanate, azide, and hydroxyl. Tetrahedral $[CoX_2L_2]$ complexes are formed by a combination of two such ligands with two neutral ligands (L). Addition of cyanide to a solution of Co^{2+} produces a dark green color attributed to the $[Co(CN)_5]^{3-}$ ion.

The colors produced by cobalt(II) complexes in aqueous media have been used to distinguish between octahedral and tetrahedral coordination in the complexes. In general, octahedral species are pink to violet, whereas tetrahedral species are blue. This is not an infallible distinction, but it does provide a useful guide that can be improved by analyzing the electronic spectra of the complexes.

Cobalt(III) Compounds. In addition to the mixed-valence oxide Co_2O_3, impure forms of the unstable cobalt(III) oxide, Co_2O_3, have been prepared. Very few simple cobalt(III) salts are known. The blue sulfate, $Co_2(SO_4)_3 \cdot 18\,H_2O$ [*13478-09-6*], which contains the $[Co(H_2O)_6]^{3+}$ species, can be obtained by the electrolytic oxidation of cobalt(II) in 4M sulfuric acid solution. It is stable when dry, but decomposes in the presence of moisture. The alums $MCo^{III}(SO_4)_2 \cdot 2\,H_2O$ (M = K, Rb, Cs, NH_4) are also known, and a hydrated fluoride $2\,CoF_3 \cdot 7\,H_2O$ has been reported.

The chemistry of cobalt(III) is dominated by complex formation. Cobalt(III) complexes are kinetically inert, and for this reason, indirect methods of syntheses are used to obtain them. Usually the ligand is added to a solution of Co^{2+}, which is then oxidized with some convenient oxidant, often in the presence of a catalyst such as activated charcoal. A wide range of cobaltammines have been prepared and studied; the species identified in solution or as solid derivatives include $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_5H_2O]^{3+}$, $[Co(NH_3)_5X]^{2+}$ (X = Cl, Br, NO_2, NO_3), and *cis*- and *trans*-$[Co(NH_3)_4X_2]^{+}$ (X = Cl, NO_2).

In addition to these simple cobaltammines, a number of polynuclear species containing bridging groups such as NH_2^-, NH^{2-}, NO_2, OH^-, and O_2 have been prepared. Polynuclear cobaltammines that have been identified include:

Complexes of cobalt(III) with O-donor ligands are generally less stable than those with N-donor species, although $[Co(acac)_3]$ [*14024-48-7*] and $[Co(C_2O_4)_3]^{3-}$ are known. Apart from the O_2-bridged compounds mentioned above, the octahedral fluoro complexes $[CoF_6]^{3-}$ and $[CoF_3(H_2O)_3]$ are the only known high-spin cobalt(III) complexes, the paramagnetic moment of $[CoF_6]^{3-}$ at room temperature being about 5.8 μ_B. All other cobalt(III) complexes are low-spin and diamagnetic, including the hexacyanocobaltates (III), $[Co(CN)_6]^{3-}$, and the hexanitritocobaltates(III), $[Co(NO_2)_6]^{3-}$.

In addition to the two most stable oxidation states, 2+ and 3+, cobalt also forms compounds in the 1−, 0, 1+, and 4+ oxidation states. There are only a few reported examples of Co^{IV} [*20499-79-0*] compounds, mainly fluoro complexes, $[CoF_6]^{2-}$, and mixed-metal oxides (the purity of compounds in this oxidation state is questionable).

The formation of cobalt compounds in oxidation states lower than 2+ requires the presence of stabilizing π-acceptor ligands. The 1+ state [*16610-75-6*] is not common for cobalt, and most of the known examples are pentacoordinated complexes of the type $[Co(NCR)_5]^+$ (NCR = organic nitrile). Cobalt forms a wide range of complexes in which its formal oxidation state is 0 or 1 – [*16727-18-7*]. Many of these contain ligands such as CO, CN^-, NO^+, and RNC, but other ligands such as tertiary phosphines also stabilize lower oxidation states to give compounds like $[Co(P(CH_3)_3)_4]^+$, which is prepared by reducing an ethereal solution of cobalt(II) chloride with sodium or magnesium amalgam in the presence of trimethylphosphane.

Cobalt Carbonyls [19, 20]. The carbonyl complexes of cobalt are important because of their uses as hydroformylation catalysts (see Section 7.3.3). Because cobalt has an odd number of valence electrons, it can only satisfy the eighteen-electron rule in its carbonyls if Co – Co bonds are formed. For this reason, the principal binary carbonyls of the element are octacarbonyldicobalt [*15226-74-1*], $[Co_2(CO)_8]$, dodecacarbonyl-tetracobalt [*19212-11-4*], $[Co_4(CO)_{12}]$, and hexadecacarbonylhexacobalt [*12182-17-1*], $[Co_6(CO)_{16}]$.

Octacarbonyldicobalt is prepared by heating the metal to 250 – 300 °C at 200 – 300 bar of carbon monoxide or by heating cobalt carbonate under similar conditions in the presence of hydrogen. It is an air-sensitive orange-red solid with a melting point of 51 °C. The compound can be reduced with sodium amalgam in benzene to give the tetrahedral monomeric ion $[Co(CO)_4]^-$, acidification of which leads to tetracarbonylhydridocobalt [*16842-03-8*], $[HCo(CO)_4]$. This hydride is a yellow liquid that forms a colorless vapor. It melts at – 26 °C and decomposes above this temperature to H_2 and $[Co_2(CO)_8]$. It is partly soluble in water to give a strong acid solution containing $[Co(CO)_4]^-$ ions. The hydrogen atom in $[HCo(CO)_4]$ is bound directly to the cobalt, giving a Co – H infrared stretching frequency of ca. 1934 cm^{-1}. The $[Co(CO)_4]^-$ ion is reoxidized to $[Co_2(CO)_8]$ by carbon tetrachloride, and further reaction with this reagent leads to a triply bridged chloromethynyl derivative, from which a carbidocarbonyl compound, disodium carbidopentadecacarbonylhexacobaltate, $Na_2[Co_6C(CO)_{15}]$, can be obtained:

$$10\,[Co_2(CO)_8] + 6\,CCl_4 \xrightarrow[\text{90 \% yield}]{40\,^\circ C} 4\,[Co_3(CO)_9(CCl)] + 8\,CoCl_2 + 44\,CO + C_2Cl_4$$

$$[Co_3(CO)_9(CCl)] + 3\,Na[Co(CO)_4] \xrightarrow[\text{Propylene oxide}]{25\,^\circ C} Na_2[Co_6C(CO)_{15}] + NaCl + 6\,CO$$

Other carbidocarbonyls are obtained by similar routes, including $[Co_6C(CO)_4]^-$, $[Co_8C(CO)_{18}]^{2-}$, and $[Co_{13}(C)_2(CO)_{24}H]^{4-}$. Dodecacarbonyltetracobalt is obtained as a green black solid by heating $[Co_2(CO)_8]$ in an inert atmosphere at 50 °C.

The structure of $[Co_2(CO)_8]$ in the solid state is different from that in solution. The solid-state structure shown in Figure 5 A involves two bridging carbonyl groups and can be best rationalized in terms of the formation of a bent Co – Co bond. In solution, however, this structure is in equilibrium with the form shown in Figure 5 B, in which the dimer is held together by a Co – Co bond. The structure of $[Co_4(CO)_{12}]$ is shown in Figure 5 C. The structure of the carbidocarbonyl (Fig. 5 D) shows the presence of a carbon atom at the center of a distorted square antiprismatic cobalt cluster.

In addition to the carbonyls, cobalt also forms complexes with N_2 and NO^+, which are isoelectronic with CO. Examples of this type of complex are $[CoH(PR_3)_3(N_2)]$ and $[Co(CO)_3NO]$, where R is an alkyl group.

7.2. Commercially Important Cobalt Compounds [9, 16, 21, 22]

Table 18 lists the known applications of cobalt compounds. The most important commercially available compounds are the oxides, as well as hydroxide, chloride, sulfate, nitrate, phosphate, carbonate, acetate, oxalate, and other carboxylic acid derivatives.

Cobalt Oxides. Two main types of cobalt oxide distinguishable by their colors are available: *gray* cobalt(II) oxide, containing 75 – 78 %

Table 18. Industrial uses of cobalt compounds

Compound	CAS reg. no.	Formula	Uses
Acetate(III)	[*917-69-1*]	$Co(CH_3COO)_3$	catalyst
Acetate(II)	[*71-48-7*]	$Co(CH_3COO)_2 \cdot 4\ H_2O$	driers for lacquers and varnishes, sympathetic inks, catalysts, pigment for oil cloth, mineral supplement, anodizing, stabilizer for malt beverages
Acetylacetonate	[*14024-48-7*]	$Co(C_5H_7O_2)_3$	vapor plating of cobalt
Aluminate	[*13820-62-7*]	$CoAl_2O_4$	pigment, catalysts, grain refining
Ammonium sulfate	[*13586-38-4*]	$CoSO_4(NH_4)_2SO_4 \cdot 6\ H_2O$	catalysts, plating solutions
Arsenate	[*24719-19-5*]	$Co_3(AsO_4)_2 \cdot 8\ H_2O$	pigment for paint, glass, and porcelain
Bromide (II)	[*7789-43-7*]	$CoBr_2$	catalyst, hydrometers
Carbonate	[*513-79-1*]	$CoCO_3$	pigment, ceramics, feed supplements, catalyst
Carbonate (basic)	[*7542-09-8*]	$2\ CoCO_3 \cdot Co(OH)_2 \cdot H_2O$	chemicals
Carbonyl	[*15226-74-1*]	$Co_2(CO)_8$	catalyst
Chloride	[*7791-13-1*]	$CoCl_2 \cdot 6\ H_2O$	chemicals, sympathetic inks, hydrometers, plating baths, metal refining, pigment, catalyst
Chromate	[*24613-38-5*]	$CoCrO_4$	pigment
Citrate	[*18727-04-3*]	$Co_3(C_6H_5O_7)_2 \cdot 2\ H_2O$	therapeutic agents, vitamin preparations
Ferrate	[*12052-28-7*]	$CoFe_2O_4$	catalyst, pigment
Fluoride	[*10026-17-2*]	CoF_2	fluorinating agents
	[*10026-18-3*]	CoF_3	
Fluoride	[*13817-37-3*]	$CoF_2 \cdot 4\ H_2O$	catalyst
Fluorosilicate	[*15415-49-3*]	$CoSiF_6 \cdot 6\ H_2O$	ceramics
Formate	[*6424-20-0*]	$Co(CHO_2)_2 \cdot 2\ H_2O$	catalyst
Hydroxide	[*1307-86-4*]	$Co(OH)_2$	paints, chemicals, catalysts, printing inks
Iodide	[*15238-00-3*]	CoI_2	moisture indicator
Linoleate	[*14666-96-7*]	$Co(C_{18}H_{31}O_2)_2$	paint and varnish drier
Manganate	[*12139-69-4*]	$CoMn_2O_4$	catalyst, electrocatalyst
Naphthenate		$Co(C_{11}H_{10}O_2)_2$	catalyst, paint and varnish drier
Nitrate	[*10026-22-9*]	$Co(NO_3)_2 \cdot 6\ H_2O$	pigments, chemicals, ceramics, feed supplements, catalyst
2-Ethylhexanoate	[*136-52-7*]	$Co(C_8H_{15}O_2)_2$	paint and varnish drier
Oleate	[*14666-94-5*]	$Co(C_{18}H_{33}O_2)_2$	paint and varnish drier
Oxalate	[*814-89-1*]	CoC_2O_4	catalysts, cobalt powders
Oxide	[*1307-96-6*]	CoO	chemicals, catalysts, pigments
Oxide	[*1308-06-1*]	Co_3O_4	enamels, semiconductors
Oxides		(mixed metal)	pigments
Dilanthanum tetroxide	[*39449-41-7*]	La_2CoO_4	catalyst, anode
Tricobalt tetralanthanum decaoxide	[*60241-06-7*]	$La_4Co_3O_{10}$	catalyst
Lithium oxide	[*12190-79-3*]	$LiCoO_2$	battery electrode
Sodium oxide	[*37216-69-6*]	$NaCoO_2$	battery electrode
Dicobalt manganese tetroxide	[*12139-92-3*]	$MnCo_2O_4$	catalyst
Dicobalt nickel tetroxide	[*12017-35-5*]	$NiCo_2O_4$	catalyst, anode
Lanthanum trioxide	[*12016-86-3*]	$LaCoO_3$	oxygen, electrode
Phosphate	[*10294-50-5*]	$Co_2(PO_4)_2 \cdot 8\ H_2O$	glazes, enamels, pigments, steel pretreatment
Potassium nitrite	[*17120-39-7*]	$K_3Co(NO_2)_6 \cdot 1.5\ H_2O$	pigment
Resinate		$Co(C_{44}H_{62}O_4)_2$	paint and varnish drier, catalyst
Succinate	[*3267-76-3*]	$Co(C_4H_4O_4) \cdot 4\ H_2O$	therapeutic agents, vitamin preparations
Sulfamate		$Co(NH_2SO_3) \cdot 3\ H_2O$	plating baths
Sulfate	[*10026-24-1*]	$CoSO_4 \cdot x\ H_2O$	chemicals, ceramics, pigments
Sulfide	[*1317-42-6*]	CoS	catalysts
Tungstate	[*12640-47-0*]	$CoWO_4$	drier for paints and varnishes

Figure 5. Structures of carbonyl complexes of cobalt
A) $[Co_2(CO)_8]$ (solid state); B) $[Co_2(CO)_8]$ (solution); C) $[Co_4(CO)_{12}]$; D) $[Co_8C(CO)_{18}]$

cobalt, and *black* cobalt(II) dicobalt(III) oxide, containing 70 – 74 % cobalt.

Cobalt(II) oxide, CoO (78.66 % Co), is usually prepared by the controlled oxidation of the metal above 900 °C followed by cooling in a protective atmosphere to prevent partial oxidation to Co_3O_4. Cobalt(II) oxide has a cubic unit cell with $a = 0.425$ nm. It is insoluble in water, ammonium hydroxide, and alcohol, but dissolves in strong acids in the cold and in weak acids on heating. Cobalt oxide (CoO) absorbs a large amount of oxygen at room temperature. Cobalt(II) dicobalt(III) tetroxide, Co_3O_4 (73.44 % Co), can be prepared by the controlled oxidation of cobalt metal or CoO or by the thermal decomposition of cobalt(II) salts at temperatures below 900 °C. The cubic spinel lattice has $a = 0.807$ nm; the solid material readily absorbs oxygen at room temperature, but never transforms into cobalt(III) trioxide, Co_2O_3. The mixed-valence oxide is insoluble in water and only slightly soluble in acids.

Cobalt(II) Hydroxide. $Co(OH)_2$ (63.43 % Co) is prepared commercially as a pink solid by precipitation from a cobalt(II) salt solution with sodium hydroxide. It has a hexagonal crystal structure with $a = 0.317$ nm and $c/a = 1.46$. It is insoluble in water and alkaline solutions, but dissolves readily in most inorganic and organic acids; for this reason, it is commonly used as a starting material in the synthesis of cobalt chemicals. $Co(OH)_2$ decomposes thermally by loss of water, starting at 150 °C, to give the anhydrous oxide at 300 °C. Care must be taken to store the hydroxide in the absence of air because slow air oxidation leads to a product that is poorly soluble in weak acids.

Cobalt(II) Chloride. Cobalt(II) chloride hexahydrate, $CoCl_2 \cdot 6\,H_2O$ (24.79 % Co), is a dark-red deliquescent crystalline compound with a monoclinic unit cell ($a = 0.886$ nm, $b = 0.707$ nm, $c = 1.312$ nm, $\beta = 97°17'$). It is prepared by concentrating a hydrochloric acid solution of cobalt oxide or carbonate. The chloride is very soluble in water, alcohols, and a number of other organic solvents. The solubility of the chloride in aqueous media does, however, decrease with increasing hydrochloric acid content. The hexahydrate dehydrates thermally in three stages, giving the dihydrate at 50 °C, the monohydrate at 90 °C, and the anhydrous chloride at 130 – 140 °C.

The anhydrous chloride and the lower hydrates are very hygroscopic and transform to the

hexahydrate in a moist atmosphere. The fact that the anhydrous chloride is blue and the hexahydrate red is used as a humidity indicator in silica gel desiccants. The chloride is also used in the electroplating, ceramics, glass, chemical, agricultural, and pharmaceutical industries.

Cobalt(II) Sulfate. Cobalt(II) sulfate hexahydrate, $CoSO_4 \cdot 6\,H_2O$ (20.98 % Co), is a brownish-red crystalline compound with a monoclinic unit cell (a = 1.545 nm, b = 1.308 nm, c = 2.004 nm, β = 104.7°). It is prepared by concentrating a sulfuric acid solution of cobalt oxide or carbonate. It is an efflorescent substance and loses one molecule of water when exposed to dry air or when heated gently. The hexahydrate obtained loses water in two stages to give the monohydrate at 100 °C and the anhydrous sulfate above 250 °C. The monohydrate, $CoSO_4 \cdot H_2O$ (34.08 % Co), has been manufactured and sold commercially. Cobalt sulfates are very soluble in water and are generally more stable than cobalt(II) chlorides or nitrates; for this reason they have been widely used as sources of cobalt(II) in solution for the manufacture of chemicals and for the electroplating industries. The sulfates are also used in the ceramics, linoleum, and agricultural industries.

Cobalt(II) Nitrate. Cobalt(II) nitrate hexahydrate, $Co(NO_3)_2 \cdot 6\,H_2O$ (20.26 % Co), is a red-brown crystalline compound with a monoclinic unit cell (a = 1.509 nm, b = 0.612 nm, c = 1.269 nm, β = 119°). It is prepared by concentrating a nitric acid solution of cobalt oxide or carbonate. The hexahydrate loses water rapidly at 55 °C to give the trihydrate; the monohydrate can also be prepared. The nitrates are very soluble in water, alcohols, and acetone. Cobalt nitrate is an important source of high-purity cobalt for use in the electronics and related industries, and the compound has also found uses in the chemical and ceramics industries.

Cobalt(II) Phosphate. Cobalt(II) phosphate octahydrate [*10294-50-5*], $Co_3(PO_4)_2 \cdot 8\,H_2O$ (34.63 % Co), is obtained as a purple flocculent precipitate when an alkali-metal phosphate is added to the solution of a cobalt(II) salt. The phosphate is soluble in inorganic acids and particularly in phosphoric acid, but is insoluble in water or alkaline solutions. It is used in the paints and ceramics industries and is a component of some steel phosphating formulations.

Cobalt(II) Carbonate. Although pure $CoCO_3$ has a cobalt content of 49.57 % and a pseudohexagonal unit cell, the material available commercially is a mauve basic carbonate, $[CoCO_3]_x\,[Co(OH)_2]_y \cdot z\,H_2O$, of indeterminate composition and a cobalt content of 45 – 47 %. The basic carbonate is insoluble in water, but dissolves easily in most inorganic and organic acids. For this reason it is often used as a starting material for the manufacture of other chemicals. The basic carbonate is also used in the ceramics and agricultural industries.

Cobalt(II) Acetate. Cobalt(II) acetate tetrahydrate, $Co(CH_3CO_2)_2 \cdot 4\,H_2O$ (23.68 % Co), is a deliquescent mauve-pink crystalline compound with a monoclinic unit cell (a = 0.847 nm, b = 1.190 nm, c = 0.482 nm, β = 94.3°). It is prepared by concentrating solutions of cobalt hydroxide or carbonate in acetic acid. The tetrahydrate is soluble in water, alcohols, inorganic, and organic acids including acetic acid. The compound loses its water of crystallization at ca. 140 °C. It is used in the manufacture of drying agents for inks and varnishes, catalysts, and pigments, as well as in the anodizing and agricultural industries.

Cobalt(II) Oxalate. Cobalt(II) oxalate dihydrate, $Co(C_2O_4) \cdot 2\,H_2O$ (32.23 % Co), is obtained as a pink precipitate when oxalic acid or an alkali-metal oxalate is added to the solution of a cobalt(II) salt. The dihydrate loses water when it is heated gently in air, and at 200 °C it decomposes to cobalt(II) oxide. The oxalate is insoluble in water, slightly soluble in acids, but soluble in solutions containing ammonia or an ammonium salt. The main use of cobalt oxalate is as a starting material for the preparation of cobalt metal powders.

Cobalt(II) Carboxylates. The cobalt salts of carboxylic acids can be made by the direct reaction of cobalt powder, oxide, or hydroxide with the organic acid or by precipitation reactions involving the addition of the sodium salt of the acid to an aqueous solution of a cobalt salt, such as the sulfate. Cobalt(II) resinate, oleate, linoleate, soyate, naphthenate, ethylhexanoate,

formate, acetylacetonate, and citrate have been produced for use in a variety of applications including catalysts, drying agents, metal film production, and medical uses.

7.3. Industrial Applications of Cobalt Compounds [4, 9, 16, 21 – 24]

The more important applications of cobalt chemicals listed in Table 10 can be considered under the following headings : glasses, ceramics, and refractories; driers, paints, varnishes, and dressings; catalysts; electroplating; electronics and solid-state devices; and agricultural, nutritional, and medical uses.

7.3.1. Glasses, Ceramics, and Refractories [9, 23]

The addition of cobalt oxides to provide a blue pigment for glass, ceramics, and enamels has been used for many centuries (→ Ceramic Colorants). The level of cobalt in the final product depends on the color intensity required, but is typically 0.4 – 0.5 % for colored ceramic bodies, 0.5 % for the blue glass used in welder's goggles, and a few mg/kg in camera lens glass. A range of cobalt-containing mixed-metal oxides and cobalt tripotassium hexanitrite (a yellow pigment) is also available for use as pigments. An indication of the colors obtained from mixed-metal oxide pigments is given in Table 19. The shades of the colors also depend on the exact composition of the oxide and on the method of preparing the pigment. The compositions of some ceramic pigments are given in Table 20.

Table 19. Colors of cobalt-containing pigments

Metals in mixed-metal oxide	Color
Co Al	blue
Co P	violet
Co Zn	green
Co Sn Si	light blue
Co Cr Al	turquoise
Co Mg	pink
Co Fe	brown

Table 20. Compositions of cobalt-containing pigments

Color	Content of Co_3O_4, %	Content of other components (% in parentheses)
Mazarine blue	68.0	SiO_2 (12), cornish stone (16), $CaCO_3$ (4)
Willow blue	33.3	$CaCO_3$ (50), SiO_2 (16.7)
Dark-blue	44.6	Al_2O_3 (55.4)
Matt blue	20.0	Al_2O_3 (60), ZnO (20)
Blue-green	41.8	Al_2O_3 (39), Cr_2O_3 (19.2)
Black	20.6	Fe_2O_3 (41.1), Cr_2O_3 (32.4), MnO_2 (5.9)

The pigments are normally prepared by mixing the ingredients as oxides or as readily decomposable salts and then calcining the mixture at 1100 – 1300 °C prior to milling the product to obtain the pigment as a fine powder. In ceramic applications, the pigments can be added to the ceramic base materials to give a body color or, after being mixed with suitable fluxes, applied as an underglaze (as on Delft china), or overglaze decoration. The final shade after the ceramic has been fired may be modified by reaction between the pigment and the clay base.

Cobalt pigments are used for decolorizing both glass and pottery articles that contain iron oxide, which would give a yellow coloration to the products in the absence of a decolorizer. The yellow color is masked by the complementary blue color of the cobalt pigment added. The levels of cobalt required for the compensation of iron oxide colorations in typical pottery bodies, enamels, and glasses are 0.003 – 0.02 %, 0.002 – 0.01 %, and 1 – 2 mg/kg, respectively. Cobalt compounds have also been used to remove color that can arise in the polymerization of poly(ethylene terephthalate) used in clear plastic bottle manufacture.

The color of the pigments and of the compounds used for decolorizing arise from the optical absorption spectra of cobalt atoms modified by lattice effects in the pigments and in the final products.

In the vitreous enameling of steel sheet, a small amount of cobalt oxide (0.15 – 1.0 %) is included in the ground coat mixture of feldspar, sand, borax, and soda ash to improve the adhesion of the enamel to the steel. As generally accepted, the cobalt does not contribute directly to the adhesion process, but it is involved in cre-

ating suitable conditions for the development of good adhesion.

Ceramic coatings for low-carbon and low-alloy steels for high-temperature use can consist of a mixture of aluminum oxide and two cobalt coats, one of which is high-firing and the other low-firing. The purpose of the latter is to seal off oxygen at low temperatures to protect the base metal from oxidation from the start of the firing. These coatings are claimed to withstand combustion products and corrosive vapors up to 750 °C and have been used to protect flue gas and gas turbine exhaust pipes.

The metal – glass coatings used to protect plain carbon steels typically contain 80 % powdered chromium and 20 % of a borosilicate glass containing 5 % cobalt oxide. Superalloys have also been coated with a ceramic consisting of high-firing cobalt ground coats with high aluminum oxide content or with boron nitride containing a lithium cobalt oxide binding agent.

7.3.2. Driers, Paints, Varnishes, and Dressings [9]

A number of cobalt pigments have been used in oil paintings, including Cobalt blue smalt [*1345-16-0*] (a silicate), Thenard's blue [*13820-62-7*] (an aluminate), Cerulean blue [*68187-05-3*] (a stannate), Cobalt violet [*82196-89-2*] (a phosphate), and Aureolin yellow [*13782-01-9*] (potassium cobalt(III) nitrite). Some of the pigments have also been used for inks, for printing on fabrics and paper, and for coloring plastics.

Cobalt acetate is used for coloring the oxide layers in anodized aluminum to give shades varying from bronze to black. The anodized metal is immersed in a 20 % solution of cobalt acetate and then either in a solution of ammonium sulfide to produce cobalt sulfide (black) or in a solution of potassium permanganate (bronze). The different depths of bronze shades are achieved by different numbers of alternate immersions in the cobalt acetate and permanganate solutions. In addition to its use as a coloring agent, cobalt acetate is also used to improve the lightfastness of anodized aluminum dyed with organic pigments.

The cobalt(II) salts of a number of organic acids have been used as drying agents for unsaturated oils in paints, varnishes, and inks. The salts used for this purpose include the oleate, ethylhexanoate, naphthenate, soyate, linoleate, resinate, and tallate. These cobalt salts are either soluble in the unsaturated oils or they react with them to form soluble compounds that then act both as oxidation accelerators of the oil and as polymerization catalysts, forming a film with increased stability, resistance, and flexibility. The drying action is due entirely to the redox behavior of the cobalt species present; the carboxylate moieties simply act as oleophilic groups to solubilize the cobalt compounds in the oils. The amounts of cobalt added to the oils as drying agents are in the range 0.01 – 0.6 %; the salts can be added as solutions in organic solvents or as dispersions of ultrafine powders (→ Drying Oils and Related Products). Cobalt-containing drying agents are also used in low-temperature curing processes for silicone resins. The cobalt species promote drying at the surface of the film in contact with atmospheric oxygen. Its action is so fast that a hard polymeric film can be formed that prevents deep drying; for this reason cobalt is often used in conjunction with other metals such as zinc and calcium that do not have a drying action but slow down and control the effects of cobalt.

7.3.3. Catalysts [24]

Cobalt compounds are versatile catalysts. Cobalt-containing materials have been used to catalyze the following types of reactions: hydrogenation; dehydrogenation; hydrogenolysis including hydrodenitrification and hydrodesulfurization; hydrotreatment of petroleum products; selective oxidation; ammonoxidation; oxidation; hydroformylation; polymerization; selective decomposition; and ammonia synthesis. In addition to these more general reactions, there are a number of reactions for which cobalt chemicals are among the best catalysts. These include their uses as driers, described in Section 7.3.2., their use in the oxidation of ammonia to nitric acid, and the syntheses of fluorocarbons.

The effectiveness of cobalt as a catalyst is related to the ease with which the element forms complexes and particularly to the large variety of ligands in these complexes.

The main industrial processes using cobalt catalysts are the removal of sulfur from vari-

ous petroleum-based feedstocks (hydrodesulfurization), selective liquid-phase oxidation, and hydroformylation. The catalysts used in the hydropurification reactions including *hydrodesulfurization* consist of cobalt and molybdenum oxides supported on an inert material such as alumina and contain 2.5 – 3.7 % cobalt. The homogeneous catalysts used in the *liquid-phase oxidation* processes are soluble cobalt(II) carboxylates such as acetate, naphthenoate, and oleate. Relatively large concentrations of cobalt (0.1 – 1 %) are used as cobalt salts in the catalysis of *hydroformylation* reactions in which $[HCo(CO)_4]$ is the active material. The amounts of cobalt catalysts used in hydrodesulfurization, oxidation, and hydroformylation have been estimated at 800 – 1800, 200, and 800 t/a, respectively.

In *hydrotreating,* the cobalt – molybdenum catalysts function in the sulfide form and catalyze two reactions, hydrogenation and hydrogenolysis of carbon – heteroatom bonds. Two theories have been used to explain the enhanced catalytic activity obtained by having both cobalt and molybdenum oxides in the catalysts: the *pseudointercalation model* and the *remote control model.* The first model assumes an association between molybdenum sulfide (MoS_2) and cobalt to produce active sites for the catalysis. The remote control model, on the other hand, assumes that active centers are created in the MoS_2 lattice by a mobile species of hydrogen produced at a cobalt sulfide component. The cobalt in the catalyst thus controls the nature and the number of catalytically active sites formed.

The types of *oxidations* catalyzed by cobalt salt solutions include *p*-xylene to terephthalic acid, cyclohexane to adipic acid, and hydrocarbons or acetaldehyde to acetic acid. All of these liquid-phase oxidations follow classical radical chain mechanisms. The following reaction mechanism for cyclohexane oxidation shows the role of cobalt in decomposing the hydroperoxides formed in the reaction and thus avoiding unwanted side reactions:

Initiation:

$$C_6H_{12}+R\cdot \rightarrow C_6H_{11}\cdot + RH$$

Chain reaction:

$$C_6H_{11}\cdot + O_2 \rightarrow C_6H_{11}OO\cdot$$

$$C_6H_{11}OO\cdot + C_6H_{12} \rightarrow C_6H_{11}OOH + C_6H_{11}\cdot$$

Hydroperoxide decomposition:

a) $C_6H_{11}OOH \longrightarrow$ cyclohexanone + H_2O

b) $Co^{2+} + C_6H_{11}OOH \longrightarrow Co^{3+} + C_6H_{11}O\cdot + OH^-$
$Co^{3+} + C_6H_{11}OOH \longrightarrow Co^{2+} + C_6H_{11}OO\cdot + H^+$
$\longrightarrow$ chain

c) $C_6H_{11}OOH$ + all radicals $\longrightarrow$ degradation products, cyclohexanol, and cyclohexanone

In *hydroformylation* and *hydroesterification,* oxo reactions such as those listed below occur (→ Carbonylation; → Oxo Synthesis):

$$CH_3OH + CO \rightarrow CH_3COOH$$

$$RCH=CH_2 + CO + H_2 \rightarrow RCH_2CH_2CHO$$

$$RCH=CH_2 + CO + 2H_2 \rightarrow RCH_2CH_2CH_2OH$$

$$RCH=CH_2 + CO + R'OH \rightarrow RCH_2CH_2COOR'$$

The cobalt salts added to the reaction mixture are converted into $[HCo(CO)_4]$, which catalyzes the oxo reaction by the following types of mechanism:

$$[HCo(CO)_4] + RCH=CH_2 \rightarrow [RCH_2CH_2Co(CO)_4]$$

$$[RCH_2CH_2Co(CO)_4] + CO \rightarrow [RCH_2CH_2CO-Co(CO)_4]$$

$$[RCH_2CH_2CO-Co(CO)_4] + H_2 \rightarrow RCH_2CH_2COH + [HCo(CO)_4]$$

In addition to the main types of reactions catalyzed by cobalt species, cobalt compounds have also been used as catalysts for automobile exhaust gas purification, for the manufacture of nitric acid, for heterogeneous oxidation reactions, and for the oxidation of toluene to benzoic acid. Cobalt(II) dicobalt(III) tetroxide is one of the

most effective catalysts for the oxidation of carbon monoxide and also has a high activity in oxidizing nitrogen monoxide; these properties have led to the use of Co_3O_4 and the $LaCoO_3$ (perovskite phase) as components of exhaust gas purification catalysts. The oxide Co_3O_4 is also a highly selective catalyst in the oxidation of ammonia to nitric acid, although it loses activity due to sintering after repeated use and due to poisoning by sulfur dioxide.

Cobalt is often cited in the patent literature as an additive in nearly all heterogeneous oxidation catalyses, including the oxidations of propene, butane, butenes, and methanol. New systems containing cobalt can also be used to catalyze the conversion of thiols to disulfides in gasoline sweetening.

Cobalt compounds have considerable potential in *homogeneous catalytic systems* and are used with copper in the oxidation of toluene to benzoic acid; good selectivities for the conversion of methanol to ethanol have been achieved by using cobalt cluster catalysts.

Cobalt fluoride can be used as a catalyst in the *fluorination* of hydrocarbons. These reactions utilize the cobalt fluoride as a fluorine carrier and take place in two steps – oxidation of CoF_2 to CoF_3 at 150 – 200 °C followed by fluorination of the hydrocarbon at 250 – 350 °C. Both stages of the reaction are exothermic, and careful control of the reaction is needed to obtain optimum yields.

Cobalt has been a component of the catalysts used in the *Fischer – Tropsch synthesis* of hydrocarbons from synthesis gas. The mixed cobalt – thorium oxide – magnesium oxide – kieselguhr catalyst (100 : 5 : 8 : 200), for example, is generally prepared by boiling solutions of sodium carbonate containing cobalt and thorium nitrates to precipitate the metals as carbonates prior to adding magnesium oxide and kieselguhr. The mixture of metal carbonates and support materials is then filtered off, washed, dried, milled, and reduced in a hydrogen atmosphere to produce the Fischer – Tropsch catalyst.

Raney cobalt can be prepared by leaching a finely powdered aluminum – cobalt alloy containing 40 – 50 % cobalt with sodium hydroxide at 15 – 20 °C, which dissolves the aluminum to leave a very active porous cobalt residue. The properties of Raney cobalt are similar to those of Raney nickel, and the materials can be used to catalyze the same types of reaction.

7.3.4. Electroplating [9]

Cobalt is readily electrodeposited from a number of electrolyte solutions. Pure plated layers of cobalt are of little commercial value, but cobalt is an important component of a number of alloy electrodeposits. The electrochemical equivalent of cobalt is 1.099 g A^{-1} h^{-1} and, with cathode efficiencies of 90 – 100 % for most electrolytes, the deposition rates are ca. 1 g A^{-1} h^{-1}. Solutions of cobalt sulfate, chloride, sulfamate, or fluoroborate have been used as electrolytes. The compositions of typical plating baths are listed in Table 21. To obtain a smooth metal deposit at a cathode efficiency of 90 – 100 % and a current density of 5 A/dm^2, the bath should have a high cobalt ion concentration (65 – 100 g/L) and should be operated at a temperature of 25 – 50 °C and a pH of 4 – 5.

Additions of cobalt sulfate to nickel plating baths have been used to produce bright nickel plates consisting of nickel – cobalt alloys. The proportion of cobalt in the electrolyte controls the composition of the alloy deposited. Since the deposition potential of cobalt is less than that of nickel, the cobalt – nickel ratio is higher in the deposit than in the electrolyte. A typical bath composition is given in Table 21. If this bath is operated at 55 – 60 °C, pH 4 – 4.3, and with a current density of 2.5 – 4 A/dm^2, an alloy deposit containing 18 % cobalt is produced. The cobalt content of the bath must be maintained by the addition of the cobalt salt when nickel anodes are used. Cobalt sulfamate is used as an alternative to cobalt sulfate in some chloride – sulfate nickel plating baths.

Cobalt – tungsten alloys with tungsten contents of up to 10 % can be deposited from baths containing cobalt sulfate and sodium tungstate (typical electrolyte composition given in Table 21). A temperature of 70 – 90 °C and a pH of 7 – 9 are used to obtain smooth crack-free cobalt –tungsten deposits. Cobalt – molybdenum alloys can be obtained under similar conditions when sodium molybdate replaces the sodium tungstate in the electrolyte. A number of other cobalt-containing alloys can be obtained as electrodeposits, including cobalt – iron, cobalt –

Table 21. Compositions of cobalt-containing plating baths

Electrolyte composition			Content,	Metal
Metal salts	Content, g/L	Additives	g/L	deposited
$CoSO_4 \cdot 7\,H_2O$	332	H_3BO_3	30	Co
$CoCl_2 \cdot 6\,H_2O$	300	H_3BO_3	30	Co
$CoSO_4(NH_4)_2SO_4 \cdot 6\,H_2O$	200	H_3BO_3	25	Co
$Co(SO_3NH)_2 \cdot 4\,H_2O$	450	$HCoNH_2$	30*	Co
$Co(BF_4)_2$	116 – 154	H_3BO_3	15	Co
$NiSO_4 \cdot 7\,H_2O$	240	H_3BO_3	30	Co – Ni
$NiCl_2 \cdot 6\,H_2O$	45	$NaHCO_2$	35	Co – Ni
$CoSO_4 \cdot 7\,H_2O$	3 – 15			
$CoSO_4 \cdot 7\,H_2O$	150	NaCl	28	Co – W

		Na heptanoate	100	Co – W

* mL/L.

platinum, cobalt – gold, and cobalt – phosphorus.

Electrodeposited cobalt and cobalt alloys have been used as matrices for composite wear-resistant coatings in systems that codeposit suspended particles of materials such as alumina and silicon carbide with the plating metal.

7.3.5. Electronics, Solid-State Devices, and Batteries [16, 22]

Since 1990 there has been increasing interest in the use of cobalt-containing materials in the electronics industry. The most important applications are magnetic recording and batteries.

Cobalt-containing magnetic recording media are of two types, (1) oxide or metal particles and (2) metal films. Cobalt-modified iron oxide particles are presently the predominant material in video tapes, while cobalt and particularly cobalt-chromium alloys are used in perpendicular recording applications. In digital storage of optical data and bubble memories, high recording densities are required, and cobalt alloys such as Gd – Co or Gd – Fe – Co are used in these magneto-optic devices.

The three major types of high energy density battery use substantial amounts of cobalt, and the expected consumption of the metal for this application is about 3000 t/a. All lithium ion batteries use *p*-type semiconductor $LiCoO_2$ as the positive electrode active material to operate in the range around 4 V that is unique to this type of battery. The purpose of the lithium cobalt oxide phase is to achieve charging and discharging by the reversible exchange of Li between an LiC_6 electrode and the Li^+ ions in the oxide lattice. The electrochemical reactions in Ni – Cd storage batteries involve the reduction of Ni(III) to Ni(II) and the oxidation of another metal species during discharge with the reverse reactions occurring during charging. When Co is used as the other metal in the cell the discharge reaction is:

$$Co + 2\,NiO\,(OH) + 2\,H_2O \rightarrow Co(OH)_2 + 2\,Ni(OH)_2$$

The cobalt in these cells is part of a porous positive electrode formed by impregnating Ni powder on a perforated metal foil with co-precipitated nickel and cobalt hydroxides. Cobalt is an important component of both electrodes of nickel/metal hydride rechargeable batteries. In the hydride electrode, cobalt reduces the volume change during the hydrogenation – dehydrogenation cycles and is an important component of the protective surface layer formed on the electrode. Both functions improve the electrode stability by minimizing corrosion and decrepitation and are essential factors in determining the cycle life of the cells. In the positive electrode the presence of cobalt helps to reduce the effects of swelling on the sintered nickel electrodes. The advantages of using cobalt along with nickel in the Ni – Cd and Ni hydride batteries stem from three factors: The similarities between the crystal structures of cobalt and nickel compounds, the greater ease of oxidation of Co(II) compared with Ni(II), and the higher electrical conductivities of cobalt oxide phases.

Black cobalt oxide, Co_3O_4, is a selective coating material for high-temperature solar collectors. The cobalt oxide coatings are superior to the black chrome coatings often used. The function of cobalt oxide as a coating intended to operate up to 1000 °C is to concentrate the solar radiation on the collector surface by a factor of up to 2000. For this purpose, a high solar absorbance with low infrared emittance is required. Cobalt oxide coatings can be prepared by plating, pyrolysis of cobalt salts on heated substrates, vacuum deposition, and by use of Co_3O_4-based paints. Table 22 gives absorbance and emittance data for cobalt oxide coated solar panels prepared in a variety of ways on different substrates.

Cobalt(II) oxide has been used in thermistors to improve both the resistivity and the temperature coefficient of the resistivity of the device. A number of mixed-metal cobalt oxides have been used in devices, including $NiCoO_4$ and La_2CoO_4 as anodic materials in water electrolysis, $NaCoO_2$ as cathodes in sodium batteries, and $CoMoO_4$ as a fuel cell electrode.

7.3.6. Agriculture, Nutrition, and Medicine [21]

Cobalt chemicals are used to correct cobalt deficiencies in soils and in animals. Soil treatments usually involve top dressings containing cobalt sulfates, whereas treatment of ruminant animals involves the use of either salt licks containing ca. 0.1 % of cobalt as sulfate, or concentrated feeds, or pellets of cobalt oxide bound in an inert material such as china clay.

The medicinal uses of cobalt are dominated by the use of vitamin B_{12}. The vitamin is obtained from the mother liquors of the microbial formation of antibiotics such as streptomycin, aureomycin, and terramycin after the removal of the antibiotic. Vitamin B_{12} and cobalt treatments are used as remedies in certain types of anemia (→ Vitamins). Cobalt salts, administered intravenously, have been used as an antidote in cyanide poisoning.

The mechanisms of the agricultural and medicinal uses of cobalt chemicals are discussed in Chapter 10 of this article.

8. Analysis [25, 26]

Cobalt can be determined gravimetrically as anthranilate, as Co_2O_3 or Co after precipitation of the 1-nitroso-2-naphthol complex and subsequent decomposition, and as a pyridine thiocyanate. Volumetric methods include the use of 8-hydroxyquinoline, ethylenediamine tetraacetic acid (EDTA), and iron(III) cyanide solutions as titrants. In the case of complexometric methods, cobalt is often back-titrated with magnesium or zinc solutions after an excess of EDTA has been added. The metal can also be determined by electrodeposition on perforated platinum electrodes.

Trace levels of cobalt in most materials can be determined by a number of instrumental techniques, including X-ray fluorescence, activation analysis, atomic absorption, atomic emission, and polarography. The reagents that can be used to measure cobalt by colorimetry include dimethylglyoxime, dithizone, 8-hydroxyquinoline, nitrosonaphthols, diethyldithiocarbamate, and tripyridyl.

9. Economic Aspects [4, 27]

Although in the third quarter of the 20th century, cobalt production was very dependent upon the situation in African countries, this dependence has been eliminated with the increase in production in the rest of the world. In the period 1970 – 1979, over 70 % of available production came from Zambia and Zaire, but this had been reduced to about 33 % by 1998. The statistics for cobalt production by the major producer companies and by other countries are given in Table 23 for the period 1992 – 1997. These supply figures can be compared with the current demand for the metal (excluding demand in the CIS) of about 29 500 t. Estimated demand by end use for 1998 was: superalloys (24.3 %), hardfacing and other alloys (6.9 %), magnets (8.5 %), hardmetals (15.2 %), catalysts (8 %), pigments (11.5 %), batteries (9.5 %)), tires and driers (11 %), other chemicals (5.1 %). Some forecasts suggest that the cobalt consumption could double in the period up to 2012 and that the price sensitivity to any such increase will depend on the speed with which new sources of cobalt from laterite ores are developed. The marginal cost of production

Table 22. Properties of cobalt oxide coated solar panels

Coating method	Substrate	Absorbance, %	Emittance, %
Plated	Cu, Ni	93	28
Plated	Ni-plated steel	90	7
Plated/thermal decomposition	Ag-coated steel	> 90	20
Plated	Ni	95	–
Plated	Cu-coated steel	96	13
Oxidized paint	Al	91	30
Paint	Ni alloy	85	10
Spray pyrolysis	Al, galvanized Fe	91, 92	13, 12
Spray pyrolysis	Stainless steel	93	14

has been estimated at about $ 6 per pound. The cobalt price (for 99.8 % metal) has fluctuated from a low of about $ 7.8 per pound in 1990 to peaks of between $ 30 and $ 35 in 1992 and 1996 to $ 15 – 16 per pound in 1999.

10. Toxicology

Distribution in the Environment. Data on the distribution of cobalt in the environment have been reviewed [29, 30]. Cobalt concentrations in ambient air are exceedingly low; in remote areas atmospheric concentrations are below 1 ng/m^3, in urban environments in the range of 1 – 10 ng/m^3, and in the vicinity of cobalt processing industries above 10 ng/m^3. The cobalt content of soils is in the range of 5 – 70 mg/kg; the average is estimated to be 8 mg/kg. In fresh water, cobalt concentrations are generally low, between 0.1 and 10 µg/L [29], but considerably higher in the vicinity of metal mining and processing industries. Cobalt is mobilized into surface waters by weathering of rocks and transported into the oceans, where it is mainly coprecipitated with iron as hydroxide. Hence, the cobalt concentration in ocean waters is very low (ca. 2 ng/L) and cobalt is enriched in deep-sea sediments.

Radioactive cobalt isotopes, especially ^{60}Co, have been released into the environment from nuclear power plants, radioactive waste dumping, and nuclear accidents (Chernobyl). Because health effects of ^{60}Co are predominantly attributable to radiation and not chemical properties of cobalt, radioactive cobalt is not treated here and readers are referred to other sources, e.g., the U.S. Toxicological Profile for Cobalt [30].

Nutrition. Levels of cobalt in drinking water usually are very low (0.1 – 5 µg/L) and do not significantly contribute to the human supply of cobalt [30, 31]. The human dietary intake of cobalt varies depending on the type of food [30]. Relatively high concentrations of about 1 mg/kg dry matter (d.m.) are found in cocoa, tea, and coffee. Green vegetables and unprocessed cereals have cobalt contents ranging between 10 and 600 µg/kg d.m., and meat and fish contain only 1 – 50 µg/kg d.m. The total human intake of cobalt is estimated to be about 10 – 30 µg/d [29]. The cobalt content of nutrients has gained much attention because of the role of cobalt as the central constituent of vitamin B_{12} (cobalamin). This vitamin is the only utilizable form of cobalt, whereas inorganic cobalt is of no use for mammalian health. Vitamin B_{12} occurs almost entirely in food of animal origin, and it constitutes only a small fraction of the total cobalt in the human diet. The recommended human intake for vitamin B_{12} is 2.5 – 5 µg/d, corresponding to only 0.1 – 0.2 µg Co/d [29, 30].

Essentiality and Toxicity.

Essentiality. Inorganic cobalt is essential for the nutrition of ruminants, which require cobalt for the bacterial biosynthesis of vitamin B_{12} in their rumen (first stomach). The normative cobalt requirement of ruminants is 0.13 mg/kg feed d.m. [32]. Additions of 2 – 4 mg/d to the feed of sheep and 20 mg/d to the feed of cattle are tolerated, whereas larger doses are toxic [29]. Vitamin B_{12} deficiency in humans causes pernicious anemia. This is a very rare disease and has been observed only with strict vegetarians after decades because of the long half-life of the vitamin in the body. The symptoms of the

disease are neurological and mental defects and low erythrocyte counts.

Resorption, Distribution, and Elimination. After oral uptake, the absorption of cobalt occurs in the small intestine by the iron uptake system. In the blood, cobalt ions are preferentially bound to serum albumin and distributed to the organs [29]. The average concentrations in human organs are 0.09 µg/L in whole blood, 0.25 µg/L in urine, and 42.3 µg/kg in liver. The liver is the main location of vitamin B_{12}; it contains about 50 – 90 % of the total human vitamin B_{12} content [29].

After inhalation by exposed workers of cobalt metal dust or sparingly soluble cobalt compounds, these are taken up by lung macrophages, solubilized, and resorbed from the lung into the blood and excreted via the urine. Elevated internal concentrations of cobalt have been found in workers of the cobalt and hard metal industries [30, 31]. Inorganic cobalt is excreted slowly via the kidney with half-lives up to 90 d. Vitamin B_{12} is retained even longer with a half-life of about 400 d [29].

Toxic Effects.

Oral Toxicity. Oral toxicity of cobalt compounds has been observed rarely. After administration of high doses of cobalt chloride (100 mg/d) as a remedy for certain forms of anemia, adverse side effects on the alimentary tract were observed [30, 31]. Severe outbreaks of cardiomyopathy were recorded among heavy consumers of beer fortified with cobalt as an foam-controlling agent [30, 31]. Also, in experimental animals, the acute oral toxicity of cobalt is moderate. The oral LD50 values for various inorganic cobalt salts ranged from 150 to 500 mg/kg body weight (b.w.) for the anhydrous compounds, corresponding to 1.5 – 3 mmol Co/kg b.w. [30, 31].

Skin Sensitization. Repeated dermal exposure of metal workers to cobalt and/or cobalt compounds has resulted in a contact dermatitis manifesting as eczema and erythema [30].
